Abstract

Natural aerosols and their interactions with clouds remain an important uncertainty within climate models, especially at the poles. Here, we study the behavior of sea salt aerosols (SSaer) in the Arctic and Antarctic within 12 climate models from CMIP6. We investigate the driving factors that control SSaer abundances and show large differences based on the choice of the source function, and the representation of aerosol processes in the atmosphere. Close to the poles, the CMIP6 models do not match observed seasonal cycles of surface concentrations, likely due to the absence of wintertime SSaer sources such as blowing snow. Further away from the poles, simulated concentrations have the correct seasonality, but have a positive mean bias of up to one order of magnitude. SSaer optical depth is derived from the MODIS data and compared to modeled values, revealing good agreement, except for winter months. Better agreement for AOD than surface concentration may indicate a need for improving the vertical distribution, the size distribution and/or hygroscopicity of modeled polar SSaer. Source functions used in CMIP6 emit very different numbers of small SSaer, potentially exacerbating cloud-aerosol interaction uncertainties in these remote regions. For future climate scenarios SSP126 and SSP585, we show that SSaer concentrations increase at both poles at the end of the 21st century, with more than two times mid-20th century values in the Arctic. The pre-industrial climate CMIP6 experiments suggest there is a large uncertainty in the polar radiative budget due to SSaer.

24 Abstract

Natural aerosols and their interactions with clouds remain an important uncertainty within 25 climate models, especially at the poles. Here, we study the behavior of sea salt aerosols 26 (SSaer) in the Arctic and Antarctic within 12 climate models from CMIP6. We inves-27 tigate the driving factors that control SSaer abundances and show large differences based 28 on the choice of the source function, and the representation of aerosol processes in the 29 atmosphere. Close to the poles, the CMIP6 models do not match observed seasonal cy-30 cles of surface concentrations, likely due to the absence of wintertime SSaer sources such 31 as blowing snow. Further away from the poles, simulated concentrations have the cor-32 rect seasonality, but have a positive mean bias of up to one order of magnitude. SSaer 33 optical depth is derived from the MODIS data and compared to modeled values, reveal-34 ing good agreement, except for winter months. Better agreement for AOD than surface 35 concentration may indicate a need for improving the vertical distribution, the size dis-36 tribution and/or hygroscopicity of modeled polar SSaer. Source functions used in CMIP6 37 emit very different numbers of small SSaer, potentially exacerbating cloud-aerosol inter-38 action uncertainties in these remote regions. For future climate scenarios SSP126 and 39 SSP585, we show that SSaer concentrations increase at both poles at the end of the 21st 40 century, with more than two times mid-20th century values in the Arctic. The pre-industrial 41 climate CMIP6 experiments suggest there is a large uncertainty in the polar radiative 42 budget due to SSaer. 43

44 **1** Introduction

The polar regions have a larger sensitivity to changes in global climate than any 45 other region (Manabe & Wetherald, 1975; Meredith et al., 2019). This is called polar am-46 plification, which refers to the multiple factors that control why polar regions are chang-47 ing faster than the rest of the planet. A key reason for polar amplification is sea ice and 48 snow loss, which changes surface albedo from light to dark and induces an additional re-49 gional warming, or climate feedback (Hall, 2004). Atmospheric temperature feedbacks 50 such as the Planck feedback and local lapse-rate feedback also play an important role 51 in this amplification (Stuecker et al., 2018). Rantanen et al. (2022) found that climate 52 models and observational data disagree on the magnitude of Arctic amplification over 53 the past 40 years, with larger trends found in observations. Climate models capture some 54 aspects of polar amplification, but not all of the complexity of what is occurring within 55 the rapidly changing polar regions, in particular in the Antarctic where the model bias 56 is even more pronounced (D. M. Smith et al., 2019). 57

Clouds are a key, uncertain component of the polar and global climate system (Flato 58 et al., 2013). Specifically, clouds can have both a cooling (via reflection of shortwave ra-59 diation) and warming (by trapping longwave radiation) effect on the polar atmosphere, 60 depending on their optical thickness and cloud droplet number as reviewed in Alkama 61 et al. (2020). As a result, polar clouds in summer have the potential to dampen the ra-62 diative impact of sea ice loss through shortwave cooling (Alkama et al., 2020), but sum-63 mertime low-level clouds in the Arctic can also favor sea ice melt through longwave warm-64 ing (Y. Huang et al., 2021). In wintertime, the surface cloud forcing at the poles is stronger 65 than in summer and with a warming effect (Curry et al., 1996). 66

Aerosols are also a key uncertainty in climate models globally and have even larger 67 uncertainties in the polar regions (Sand et al., 2017). Aerosols influence the climate through 68 their interaction with radiation directly (aerosol direct effect) and their role in cloud for-69 mation/modification (aerosol indirect and semi-direct effects) (Myhre et al., 2013). Nat-70 ural sources of aerosols and their impacts on clouds have been less of a focus than un-71 derstanding anthropogenic aerosols and their direct and indirect radiative effects (Schmale 72 et al., 2021; Boucher et al., 2013; Sand et al., 2021; Samset, 2022). However, it is chal-73 lenging to separate the effects on clouds and radiation of anthropogenic and natural aerosols, 74

and these effects can have opposite signs, including at the poles (Allen & Sherwood, 2011).
In addition, cloud-aerosol interactions are non-linear (Gryspeerdt et al., 2019), so estimating anthropogenic impacts on polar clouds requires an accurate understanding of the
natural aerosol baseline. Therefore improved representation of natural aerosols and their
impacts on clouds are essential for improved anthropogenic climate change estimates.

Sea salt particles resulting from sea spray make up most of the aerosol mass over 80 oceanic regions (Andreae & Rosenfeld, 2008), with an even larger fraction over the po-81 lar regions (Sand et al., 2017). Sea spray is composed of a mixture of inorganic salts and 82 83 an organic fraction (including both dissolved organics and fragments of organic material). In this study, we focus on the inorganic fraction of sea spray emissions and use the 84 wording sea salt aerosols (SSaer) to refer to the inorganic fraction (sodium chloride, sul-85 fate, and other trace salt species) of sea spray. When discussing sea spray we refer to the 86 full mixture of emitted species, which includes both inorganic and organic marine aerosols. 87

SSaer and sulfate emitted from sea spray can act as Cloud Condensation Nuclei 88 (CCN) (Prank et al., 2022; Xu et al., 2022), and marine organics can act as Ice Nucle-89 ating Particles (INP) (Wilson et al., 2015; DeMott et al., 2016). Over polar oceans, sea 90 spray aerosols including SSaer can seasonally make up most of the cloud seeding pop-91 ulation (Quinn et al., 2017; Fossum et al., 2018). They also scatter incoming solar short-92 wave radiation directly (Takemura et al., 2002; Satheesh & Lubin, 2003). In addition, 93 SSaer also change the climate impacts of other species, including anthropogenic pollu-94 tants such as nitrate (Chen et al., 2020) and sulfate (Fossum et al., 2020), by regulat-95 ing their droplet activation. Furthermore, SSaer modulate polar atmospheric chemistry 96 by providing a surface for heterogeneous reactions and leading to bromine activation, with 97 major effects on ozone and mercury depletion events (Hara et al., 2018; Zhu et al., 2019; 98 Marelle et al., 2021). Accurately modeling sea spray aerosols, including inorganic SSaer, 99 is therefore a prerequisite for properly representing the polar atmosphere. In particu-100 lar, the SSaer physical parameters key to their cloud and radiation interaction and re-101 moval processes, are the number flux, the size distribution, and the hygroscopicity. 102

Sea spray emission over the open ocean is due to wind action that forms bursting 103 bubbles at the sea surface, visible as white caps, which emit aerosols to the atmosphere 104 (Monahan et al., 1986). The sea surface temperature (SST) can also modulate the size 105 and number of aerosols emitted (Mårtensson et al., 2003; Jaeglé et al., 2011; Salter et 106 al., 2015; Liu et al., 2021). Salinity affects the electrolytic properties of water, and as salin-107 ity increases, coalescence is inhibited and bubbles form in larger number and smaller radii, 108 which then also affects the emission flux of SSaer (Zinke et al., 2022). There remain sig-109 nificant uncertainties in the open ocean sourced sea spray aerosol emission fluxes, includ-110 ing the relatively well-studied inorganic SSaer, that is emitted into the atmosphere, es-111 pecially at the cold temperatures in the polar regions. For example, Regayre et al. (2020) 112 found that sea spray emissions in the Southern Ocean needed to be tripled in a global 113 simulation to match observations. Unlike other oceanic areas in the world that remain 114 open throughout the year, estimates of sea spray emissions at the poles depend on a proper 115 representation of sea ice cover, which is still challenging in climate models and exhibits 116 a large spread in model ensembles (Notz & SIMIP Community, 2020; Roach et al., 2020) 117 Additional polar-specific source processes of SSaer include blowing snow over sea ice (Yang 118 et al., 2008; J. Huang & Jaeglé, 2017; Yang et al., 2019; Marelle et al., 2021) and emis-119 sion fluxes specific to open water leads (Held et al., 2011; Kirpes et al., 2019; Ioannidis 120 et al., 2022). Climate models parameterize emissions from open water leads in sea ice 121 like those from the open ocean, even though wave action and white caps are very dif-122 ferent in leads than in open ocean due to e.g., reduced wind fetch, local convection, and 123 the lack of a surf zone on the sea-ice edge (Nilsson et al., 2001). Blowing snow sources 124 of SSaer on the other hand are usually not included in global models and to our knowl-125 edge are not included in CMIP6 models. 126

Due to the ongoing trend of sea ice retreat (Meredith et al., 2019), sea spray emis-127 sions at the poles are likely to increase in the coming decades. Specifically, less sea ice 128 means more open ocean and therefore more sea spray (Struthers et al., 2013). In par-129 allel, increased sea spray emissions probably have a negative effective radiative forcing 130 globally (Thornhill et al., 2021), including at the poles (Korhonen et al., 2010; Browse 131 et al., 2014), where it is likely dominated by the aerosol-cloud interaction (Struthers et 132 al., 2011). The cooling induced by SSaer-cloud interactions could partially compensate 133 for the warming caused by sea ice loss. Accurate representation of SSaer in the atmo-134 sphere is also important for reliable future climate projections. However, both AeroCom 135 (Sand et al., 2017) and the Coupled Model Intercomparison Project phase 6 (CMIP6) 136 (Mortier et al., 2020; Gliß et al., 2021) reported a large uncertainty in the aerosol bud-137 get and seasonality, globally and at the poles. Fanourgakis et al. (2019) also indicated 138 significant model diversity of up to two orders of magnitude in simulated SSAer concen-139 trations over the Southern Ocean, resulting from different parameterizations in global 140 models. 141

142

147

148

159

In the present work, we address the following science questions:

- 1. How diverse are SSaer emissions/concentrations at the poles in CMIP6 models? 143
- 2. What are the drivers of this model diversity? 144

145

- 3. How well do the CMIP6 models and ensembles represent SSaer at the poles relative to surface observations and remote sensing? 146
 - 4. What are the implications of model diversity and changes in SSaer emissions, for the present and future polar climate?

To answer these questions, we conduct an assessment of polar SSaer diversity in CMIP6 149 models in Section 3.1, by comparing SSaer related variables in the CMIP6 historical ex-150 periment. We further evaluate the models against SSaer concentration data from mea-151 surement stations and aerosol optical depth from the Moderate-Resolution Imaging Spec-152 troradiometer (MODIS) Aqua and Terra satellite products in Section 3.2. Finally, in Sec-153 tion 3.3 we analyze the historical and future trends of SSaer in the Shared Socioeconomic 154 Pathways 126 and 585 scenarios and the sensitivity of the polar radiative budget to changes 155 in SSaer emissions, through different CMIP6 experiments to shed light on the implica-156 tions of modeling discrepancies in CMIP6. 157

2 Materials and Methods 158

2.1 Models

We use results from 12 climate models that are part of CMIP6. Models were se-160 lected based the availability of relevant variables for the evaluation of SSaer. The mod-161 els included, along with the available variables and source function formulation are in-162 dicated in Table 1. Only one additional CMIP6 model features the mass mixing ratio 163 of sea salt aerosol variable (mmrss) for the historical experiment (INM-CM5). We have 164 chosen to discard this model because it produces unrealistic SSaer concentrations that 165 are three orders of magnitude larger than any other model. All other CMIP6 models are 166 excluded because they do not provide *mmrss* in the historical experiment. 167

In order to evaluate the representation polar SSaer within CMIP6 models, we ex-168 tracted the following from the Earth System Grid Federation (ESGF) platform (ESGF, 169 2014), for the historical CMIP6 experiment (run with coupled ocean-atmosphere mod-170 els) and for the period 1951–2014 (as summarized in Table 1): mass mixing ratio of sea 171 salt aerosol (*mmrss*), sea salt aerosol emission flux (*emiss*), sea ice concentration (*siconc*), 172 surface wind speed (sfcWind), optical depth of sea salt aerosol at 550 nm (od550ss) and 173 planetary boundary layer height (bldep). We use this information for all 12 models, but 174 exclude variables that were missing as output on the ESGF platform for certain mod-175

els. Future projections are also considered in this work, relying on the Shared Socioe-176 conomic Pathway (SSP) 126 and 585 experiments (ScenarioMIP activity - O'Neill et al. 177 (2016)). The significance, sign and magnitude of trends in these scenarios are calculated 178 using a Mann-Kendall test (Mann, 1945). For the evaluation of SSaer radiative impact, 179 two experiments of the AerChemMIP activity are considered. For that, the top-of-atmosphere 180 net downward radiation flux (rtmt) and near-surface air temperature (tas) in experiments 181 *piClim-2xss* and *piClim-control* pre-industrial (30 years under 1850 climate) atmospheric 182 composition scenarios are investigated. 183

184 For spatial ensemble means, model output is first re-gridded to a common grid, to the lowest model resolution available $(2^{\circ} lon \times 1.5^{\circ} lat)$. The re-gridding is done using Cli-185 mate Data Operators bilinear remapping tool (Schulzweida et al., 2012). For regionally 186 averaged numbers, a weighted mean is applied, with weights corresponding to the grid 187 cell area. Ground station data usually provide a mass concentration of sodium, whereas 188 models output the SSaer mass mixing ratio. For the comparison between the two, the 189 SSaer mass mixing ratio is therefore converted into a mass concentration under a stan-190 dard air density at 1 atmosphere and 0°C temperature $(1.2922 \, \text{kg m}^{-3})$. SSaer in the mod-191 els is assumed to follow the composition of Seinfeld and Pandis (2016), and sodium mass 192 is thus taken as 30.61% of SSaer mass. Near-surface concentration in the models refers 193 to the concentration within the lowest vertical level. Furthermore, the atmospheric life-194 time of SSaer is calculated as the global load (that is, the integral of *mmrss* on the ver-195 tical levels for each latitude and longitude) divided by the global emission rate, weighted 196 by grid cell area. We do not use deposition for the the lifetime analysis because it is only 197 available for 8 out of the 12 models. The metrics used to compare models and observa-198 tions are the normalized mean bias (NMB), defined as $NMB = (iMODEL_i - iOBS_i)/iOBS_i$. 199 where *i*, *j* is the annual mean, and the Pearson correlation coefficient, simply referred to 200 as correlation (R). 201

Among the 12 models considered, sea spray emissions are parameterized by 8 dif-202 ferent source functions or combinations of source functions (Table 1). The common fea-203 ture of these source functions is that for a given aerosol radius, the emission flux is pro-204 portional to the wind speed raised to a varying exponent. Some of the parameterizations 205 also account for the dependence of sea spray emissions on SST. Although there is still 206 debate on the exact role that SST plays in the sea spray emission process, including it 207 generally improves the fit with observations as reviewed in Grythe et al. (2014). For ex-208 ample, the Jaeglé et al. (2011) parameterization decreases emissions at colder SST, whereas 209 the Salter et al. (2015) source function does the opposite. For polar waters, for exam-210 ple, an increase in SST may decrease the number of sea spray aerosol produced, with-211 out significantly affecting the shape of the size distribution (Zábori et al., 2012). This 212 is consistent with the Salter et al. (2015) source function, but opposite to the SST de-213 pendence in the Jaeglé et al. (2011) source function, for which emissions increase at higher 214 SST. This shows that not all source functions may be fit for use in polar regions. The 215 source functions are further investigated in Section 3.1.2 based on offline calculations from 216 the source function formulations, using a sectional approach with fixed bins, regardless 217 of what is actually done in the models. This approach is used to evidence the diversity 218 coming from the source functions themselves rather than the aerosol schemes of the mod-219 els. 220

To our knowledge, polar-specific sources of SSaer such as blowing snow over sea ice 221 and emissions from leads are not taken into account in CMIP6 climate models, which 222 may limit their performance at high latitudes. Similarly, only the fraction of the ocean 223 that is ice-free can lead to sea spray emissions. Therefore, SSaer emissions at the poles 224 in climate models are highly dependent on a proper representation of sea ice cover. As 225 a consequence, SSaer emissions are probably harder to adequately model at the poles 226 than in any other oceanic region in the world. However, even for mid-latitudes and more 227 generally globally, climate models disagree on SSaer representation, such as their total 228

emission fluxes, lifetime, burden, and optical properties including hygroscopicity (Burgos 229 et al., 2020; Gliß et al., 2021). The sinks of SSaer such as dry and wet deposition, con-230 trol their atmospheric quantities. Accurate wet deposition rates require adequate pre-231 cipitation, which is challenging for Antarctica (Roussel et al., 2020) and the Arctic (Diaconescu 232 et al., 2018) in climate models. In parallel, dry deposition of aerosols is sensitive to the 233 choice of deposition velocity, which is usually not tuned for snow-covered terrain in chemistry-234 transport models, resulting in large uncertainties in the Arctic (Qi et al., 2017). Dry de-235 position is also sensitive to boundary layer stability, which is difficult to model especially 236 in polar regions (Holtslag et al., 2013). Finally, the transport of aerosols from the mid-237 latitudes to the poles can also represent a source of uncertainty in the models. There-238 fore, it is not expected that climate models would converge in regions as complex as the 239 poles, where in addition to emission fluxes, meteorology (Cai et al., 2021) and anthro-240 pogenic aerosol budgets (Sand et al., 2017) are more challenging to represent. 241

242 2.1.1 Reanalysis

In order to assess how CMIP6 models compare with more widely used air quality-243 oriented reanalyses, this work includes two monthly reanalysis products. The Modern-244 Era Retrospective analysis for Research and Applications, Version 2 (?, ?, MERRA2,)]merra2 245 and the Copernicus Atmosphere Monitoring Service (?, ?, CAMS,)]inness2019. For the 246 former, the Sea Salt Surface Mass Concentration (SSSMASS) variable from the tavq1_2d_aer_Nx 247 monthly product is considered, over the period 1980–2021. For the latter, the CAMS global 248 reanalysis (EAC4) monthly averaged fields product is used and the three size bins of the 249 Sea salt aerosol mixing ratio variable are summed and taken at the first model level, over 250 the period 2003–2021. We also use the monthly climatology of sea ice concentration from 251 the fifth generation ECMWF atmospheric reanalysis of the global climate (?, ?, ERA5,)]era5. 252

253 2.2 Observations

254 2.2.1 Ground based stations

Combining data from the literature (Legrand et al., 2016; Yang et al., 2019) and 255 from the EBAS platform (Norwegian Institute for Air Research, 2022), sodium aerosol 256 concentration measurements were obtained over a multiyear period for 9 stations in the 257 Arctic and 5 in the Antarctic. Their location, the data source, and the period covered 258 by the observations are detailed in Figure 1. When taken from the EBAS platform, the 259 weekly measurements of atmospheric sodium, typically conducted using high-volume air 260 samplers, are then averaged to obtain the annual cycle of monthly means and the related 261 standard deviations, over the entire time period in the data set. We use these observa-262 tions without assuming a particular cut-off size and directly compare to the total sodium 263 mass derived from the modeled SSaer (maximum radii in the models can be found in Ta-264 ble 1). 265

The nine Arctic stations include two sites above 80°N (Alert and Villum) in Canada 266 and Greenland, respectively. These two coastal sites are surrounded by sea ice even in 267 summer (blue contour in Figure 1). Data from a third coastal site (Utqiagvik, Alsaka, 268 71° N) is available, where, in contrast to Alert and Villum, the shore is sea ice free in sum-269 mer but sea ice covered in winter. Summit (Greenland) is an inland station in the mid-270 dle of Greenland. Zeppelin (Svalbard) is a mountainous site (475 m a.s.l.) near the shore 271 of a fjord at 79°N, which is more and more influenced by sea spray (Heslin-Rees et al., 272 2020). The rest of the Arctic stations considered in this work are in northern Europe (Irafoss 273 in Iceland, Pallas in Finland, Karasjok in Norway and Bredkälen in Sweden). For Antarc-274 tica, one of the five stations is far inland (Concordia), one is on the coast of East Antarc-275 tica (Dumont d'Urville) and the three others are in coastal western Antarctica (Halley, 276 Neumayer, Palmer). These stations are located between $65^{\circ}S$ and $75^{\circ}S$ (Figure 1). 277

278 2.2.2 Satellite remote sensing

A regional evaluation of SSaer in CMIP6 is conducted by comparing its modeled 279 optical depth with aerosol optical depth (AOD) satellite data from MODIS (Platnick, 280 2015). To our knowledge, there is no pure satellite climatology for SSaer AOD. Those 281 products available such as MACv2 (Kinne, 2019) usually include a modeled component 282 in their climatology. For the purpose of this CMIP6 model evaluation, a proxy based on 283 MODIS AOD and Angstrom exponent is therefore used to create a simple version of this 284 missing product. A more refined dedicated polar marine AOD climatology product could 285 be created by combining several satellite sources (Dror et al., 2018; Dasarathy et al., 2021; 286 Atmoko & Lin, 2022) in future work. However, the Arctic time series obtained using the 287 methodology described below (Section 3.2.2) is well in line with the SSaer AOD values 288 reported in Xian et al. (2022) for example, which are based on an ensemble of reanal-289 yses. This suggests that the simple proxy used here yields reasonable values of SSaer AOD. 290

This custom product is based on the MODIS Atmosphere L3 Monthly Products 291 MOD08_M3 (from satellite Terra) and MYD08_M3 (from satellite Aqua) (Platnick, 2015) 292 for the period 2005–2014. The monthly mean AOD at 550 nm is taken from the Dark 293 Target/Deep Blue (DTDB) combined variable AOD_550_Dark_Target_Deep_Blue_Combined_Mean_Mean. 294 Then, a filter is applied that aims at keeping only the contribution of SSaer to AOD. This 295 filter is based on the condition that the Angstrom exponent is below 1 to filter out fine-296 mode aerosols. The implied assumptions are that SSaer are dominated by coarse-mode 297 particles and that coarse-mode aerosols over the polar oceans are dominated by SSaer. 298 The former is shown in e.g. Murphy et al. (2019), the latter assumption is discussed in 299 the next paragraph. The Aerosol_AE1_Ocean_JHisto_vs_Opt_Depth variable from MOD08_M3 300 and MYD08_M3 is used to discriminate Angstrom exponents. It contains, for each month 301 and grid cell, a joint histogram of the calculated Angstrom exponent $(0.55-0.86 \,\mu\text{m})$ ver-302 sus retrieved AOD at 550 nm. This variable provides data only over oceans, and as a re-303 sult the product we build here is only valid for oceans. We use it as follows: for each grid 304 cell and month, the frequency of records with AE < 1 i.e. $Freq_{AE < 1} = Counts_{AE < 1}/Counts_{AE}$ 305 is computed, regardless of the AOD joint distribution. The DTDB 550 nm AOD is then 306 multiplied by this $\operatorname{Freq}_{AE<1}$ factor to approximate the fraction of AOD attributable to 307 coarse-mode aerosols, and by extension SSaer. The resulting estimated fraction of AOD 308 from MODIS attributed to SSaer is referred to as AODss in the continuation. The al-309 gorithm created to build this AODs extraction from MODIS is attached to this paper. 310

The key assumption for the validity of this approach is that coarse-mode aerosols 311 in the MODIS records are dominated by SSaer over polar oceans and therefore that dust 312 has a minor contribution. This hypothesis is supported by the MACv2 aerosol clima-313 tology (Kinne, 2019), which provides AOD based on AERONET/MAN and climate mod-314 els, with species differentiation. We use this data set to evaluate the contribution of SSaer 315 AOD to {SSaer+dust} AOD and assess the validity of the assumption that dust is not 316 an important fraction. In this data set, the fraction of {SSaer+dust} AOD attributed 317 to SSaer is well above 80% over most of the polar oceans, except in coastal areas where 318 important dust sources can be found (Meinander et al., 2022) and the central Arctic, which 319 is permanently covered with sea ice (Figure 1). For these regions, however, AOD in MACv2 320 is very low and/or dominated by the fine-mode fraction, which is filtered out by our Angstrom 321 exponent criterion. Therefore the MACv2 product supports the assumption that coarse-322 mode AOD over the polar oceans is essentially SSaer AOD, as illustrated in Figure A1. 323 Sporadic transport events of aerosols (volcanic ash, biomass burning, anthropogenic pol-324 lution) can also affect the signal recorded by MODIS, but we argue that such short-lived 325 events are smoothed out by the monthly averaging, except where the number of avail-326 able records is low. 327

328 **3** Results and discussion

329

3.1 Representation of polar SSaer in CMIP6

In the Arctic, the CMIP6 1951–2014 climatology of the SSaer surface mass mix-330 ing ratio (referred to as *mmrss* from now on) shows maximum values over the northern 331 Atlantic and northern Pacific (Figure 2), with the mixing ratio decreasing poleward, reach-332 ing averages below $1 \, \mu g \, kg^{-1}$ in the high Arctic. CNRM-ESM is an exception, with mix-333 ing ratios more than one order of magnitude greater than any other model. This discrep-334 ancy is discussed later on. The northward negative gradient is consistent with an increase 335 of the relative area fraction covered by sea ice as latitudes increase, which inhibits the 336 production of sea spray. Over the continents, concentrations are generally below $1 \, \mu g \, kg^{-1}$, 337 down to less than $50 \,\mathrm{ng \, kg^{-1}}$ in some models, with *mmrss* decreasing inland, in connec-338 tion with the deposition of the SSaer during transport. Therefore, all the models have 339 characteristics that are consistent with the expected behavior of SSaer production and 340 transport patterns. 341

Although the spatial distribution remains relatively consistent (Figure 2), in terms 342 of magnitude, there is a large diversity between models. CNRM-ESM appears as an out-343 lier at both poles, yielding very high mmrss of up to $900 \,\mu g \, kg^{-1}$, 20 times larger than 344 any other model. This can be explained by a larger coarse size radius of SSaer at emis-345 sion in CNRM-ESM compared to the other models, as already noted in Thornhill et al. 346 (2021). In this regard, CNRM-ESM being an outlier, this model is not included in the 347 continuation of the analysis unless explicitly mentioned. CNRM-ESM aside, GISS presents 348 the highest mixing ratios, with more than $40 \,\mu g \, kg^{-1}$ in the northern Atlantic and more 349 than $1 \mu g kg^{-1}$ over most of the high Arctic and continental areas. At the other end of 350 the spectrum, MRI-ESM and MIROC-ES2L do not exhibit mixing ratios above $10 \, \mu g \, \text{kg}^{-1}$, 351 and they drop to less than $50 \,\mathrm{ng \, kg^{-1}}$ over continental areas. This spread in magnitudes 352 will be further analyzed in Section 3.1.2 based on source functions. In some models, the 353 latitudinal gradients are sharper (e.g. BCC-ESM compared to EC-Earth) suggesting dif-354 ferent representations of atmospheric dynamics (transport, boundary layer dynamics) 355 and deposition (dry and wet). 356

For the Antarctic (Figure 3), this climatology of *mmrss* has larger values than for 357 the Arctic, due to the Southern Ocean providing a large source area of sea spray com-358 bined with strong winds. A band of maximum mmrss is found around 50°S in the South-359 ern Ocean in all the models, followed by a negative gradient toward the pole related to 360 deposition during the transport. Again, CNRM-ESM aside, GISS presents the highest 361 values, whereas MRI-ESM and MIROC-ES2L have the lowest, and the poleward gradi-362 ent is more or less sharp depending on the model. Similarly to the Arctic, CMIP6 mod-363 els give a generally consistent spatial distribution of *mmrss* in the Antarctic, except for the magnitudes, which are even more diverse. 365

The diversity in spatial gradients between models is particularly relevant for the 366 interpretation of ice cores from polar ice sheets (Greenland, Antarctica). Sea salt in ice 367 cores at coastal sites can be used as a proxy for sea ice conditions variability, but mod-368 els usually show that for continental polar areas, meteorology, atmospheric transport, 369 and deposition control sea salt in ice cores instead (Levine et al., 2014; Rhodes et al., 370 2018). The differences in transport shown here in CMIP6 models suggest that the rel-371 ative attribution of sea salt variability in ice cores to transport meteorology and changes 372 in the sea ice source can be quite uncertain. The spatial distribution is consistent from 373 one model to another, but differences in gradient suggest that the representation of at-374 mospheric dynamics and sinks (wet and dry deposition) may differ. 375

Figure 4 further summarizes the model diversity, including for other SSaer related variables. Similarly to mixing ratios, there is a large diversity in total mass emission and deposition fluxes, which partly accounts for the diversity in *mmrss*. In addition, SSaer

are not found at the same altitudes in all the models. This information is contained in 379 the aerosol layer height, which is defined as a weighted mean of SSaer layer height us-380 ing the *mmrss* of each layer as the weight (Figure 4). For CESM this height is 956 m, 381 while it is only 136 m in IPSL-CM6. This aerosol layer height is important when it comes 382 to the interaction of SSaer with clouds. The residence time (or lifetime) of SSaer is one 383 of the most diverse metric, with values between a few hours up to several days depend-384 ing on the model. This factor may explain the differences in transport over land, since 385 models with longer residence time also feature higher concentrations over Antarctica and 386 Greenland (Figures 2 and 3). These differences in lifetime can be explained by the ver-387 tical distribution of SSaer: models with longer lifetime also have higher aerosol laver height. 388 GISS is an exception in that case, but the relatively small deposition flux compared to 389 the other models compensates for the lower aerosol height and extends the residence time. 390 SSaer optical depth is also diversely represented in the models, and not directly related 391 to *mmrss*, indicating possible differences in the parameterizations of the size distribu-392 tion and hygroscopicity. We note that the GISS AOD values for SSaer are much higher 393 than other models, therefore we exclude this model from the AOD analysis that follows. 394

In summary, there is a large diversity in CMIP6 models in terms of their SSaer cli-395 matologies at the poles, from the mass emissions (factor 3 between lower and higher mod-396 els) to the surface mass mixing ratios (factor 4-5), through the aerosol layer height (fac-397 tor 7-8), lifetime (factor 9), optical depth (factor 4) and total deposition (factor 2-3). In 398 the Arctic, dry deposition is more diverse (factor 15) than wet deposition (factor 3), whereas 399 in the Antarctic, both dry and wet deposition have a similar inter-model spread (factor 400 9). This difference in variability in wet deposition might be related to the difficulty to 401 properly reproduce Antarctic precipitation in models (Palerme et al., 2017). 402

403

3.1.1 Model diversity drivers

The diversity in SSaer climatology is further investigated and explained in terms 404 of the annual cycle of *mmrss* and the associated drivers (Figure 5). *mmrss* over the ocean 405 is driven by emissions, the height of the boundary layer, and deposition rates. Emissions 406 are themselves driven by wind speed and sea ice fraction. SST also affects emissions, but 407 for consistency this variable is not included in the following analysis on annual cycles of 408 emission drivers, since only four of the models take it into account in their source func-409 tion. Here the focus is on the dynamical drivers and their effects on emissions and con-410 centrations. Figure 5 presents the annual cycle of the aforementioned variables for the 411 Arctic and Antarctic, averaged over grid points where emissions are strictly positive and 412 the open ocean fraction is at least 10%. This filter is applied to allow a fair comparison 413 across all models. 414

In the Arctic, mass emissions are consistently at their lowest in the summer months 415 (Figure 5c), when despite increasing sea ice melt and therefore increasing open ocean area 416 (Figure 5e), wind speeds are at their lowest (Figure 5g), thus limiting sea spray. All mod-417 els show similar magnitudes in summer, except for IPSL-CM6 which features greater val-418 ues. The spread is larger in the fall/winter months with a factor of up to three between 419 IPSL-CM6 and GISS on the total emission rate in October. This diversity in emissions 420 seems driven mainly by diversity in sea ice (larger spread) and then by wind speed. Fur-421 thermore, the source function formulation and size distribution of the emitted aerosols 422 are key factors that are discussed in Section 3.1.2. 423

For the winter months, when wind speeds are higher, the sea ice fraction seems to be the factor limiting emissions, while in the fall, when there is more open ocean, the wind seems to be the controlling factor. In parallel, the ongoing reduction of sea ice cover in the Arctic appears to be correlated with stronger winds in fall/winter months (Vavrus & Alkama, 2022). Therefore, in the context of future climate, the shape of the annual cycle of emissions is likely to change, with possibly an even greater amplitude between summer and fall/winter emissions. Given that the radiative impact of SSaer changes with
 seasons (Section 3.3.1), changes in the seasonality of SSaer emissions might have impor tant implications for the polar climate.

For the Antarctic (Figures 5d, f, h), the emission drivers are even more spread across models, particularly the open ocean fraction in the winter months, resulting in a diversity factor of up to 6 in total mass emissions. Unlike for the Arctic, annual cycles show different shapes in some models. For example, MIROC-ES2L and MPI-ESM show a SSaer production peak in May–Jun whereas the other models have maximum emissions in Mar– Apr, along with a sharper seasonality. In this case, the sea ice cover appears to be the reason for this diversity.

The diversity in emissions is partly translated into mmrss (Figure 5a, b) although 440 it does not account for the relative ranking of the models or for some characteristics of 441 the annual cycle. For example, GISS is the model with the lowest mass emissions in the 442 Arctic (Figure 5c), and around median emissions in the Antarctic (Figure 5d), but shows 443 the highest mixing ratios at both poles. This could result from the representation of the 444 dynamics of the boundary layer, since GISS has a mean planetary boundary layer height 445 between 300 to 500 m, about three times lower than other models (Figure 5i, j), which 446 results in a higher boundary layer concentration for the same amount of emissions. EC-447 Earth also shows very shallow boundary layer heights similar to those of GISS, along with 448 a comparatively higher emission rate at both poles, which should result in mixing ratios 449 higher than in the other models. However, those mixing ratios are lower, due to a shorter 450 lifetime of SSaer of around 14 h, while it is more than a day in GISS (Figure 4). This 451 is also reflected by a deposition flux twice as large in EC-Earth compared to GISS, where 452 the difference mostly comes from dry deposition (Figure 4). In terms of the annual cy-453 cle, in the Arctic the seasonality of the boundary layer height shows the same shape as 454 for emissions, which are both consistent across models. Therefore, the cycle of mixing 455 ratio follows the cycle of emissions. However, in the Antarctic, the planetary boundary 456 layer height cycle is more diverse, as is the case for emissions, resulting in more diverse 457 values and seasonality. Deposition fluxes and lifetimes further modify the relative rank-458 ing of models in terms of mixing ratio as shown in Figure 4, but the seasonality is not 459 affected. 460

461

3.1.2 Role of emission source functions

The source function formulations also affect the diversity in emissions. Figure 6 explores the differences in fluxes resulting from the diversity of source functions used in the CMIP6 models. The source functions and aerosol modes/bins used in the models are summarized in Table 1. All the models except NorESM use a whitecap fraction approach based on surface wind speed, but not all include a dependence on SST. Instead, NorESM uses the air-entrainment-based Salter et al. (2015) formulation.

Figure 6a shows the theoretical mass flux from an offline calculation of SSaer emis-468 sions for each source function using an arbitrary fixed wind speed and SST $(10 \,\mathrm{m\,s^{-1}}$ and 469 5° C, respectively) and varying aerosol size bins, as described in Section 2.1. Figure 6b 470 explores the effect on this flux of varying wind speed and SST for given size bins. Some 471 CMIP6 models use a modal aerosol approach, some use a sectional (size bins) aerosol 472 approach. Here, for the sake of comparability of the source functions, we use a sectional 473 approach for the aerosol sizes. Therefore, the following analysis reflects the model di-474 versity due to the source functions without considering the actual aerosol size distribu-475 tions (modal or sectional) that are included within each model. 476

Figures 2 and 3 show that CNRM-ESM has *mmrss* much higher than all the other models. This is explained by the use of the Grythe et al. (2014) source function with size bins up to 20 μ m radius. First, the other CMIP6 models only emit up to a maximum radius of ~10 μ m, so CNRM-ESM adds an extra mass in the 10 μ m-20 μ m range. Second, the Grythe et al. (2014) source function has a coarse emission mode with a mean radius of 30 μ m, inducing large emissions of coarse particles which strongly contribute to mass. Figure 6a shows that for a maximum radius of 20 μ m, this source function yields a mass flux one order of magnitude greater than any other model for a given wind speed of 10 m s⁻¹ and 5°C SST, which is the difference observed in Figure 4.

Figure 6a also shows that for a given choice of aerosol size bins (assuming a sec-486 tional approach with mean radii $0.05 \cdot 0.5 \cdot 1 \cdot R_{max} \mu m$ and varying R_{max}), selecting a source 487 function over another can change the flux by up to one order of magnitude (e.g. grey bar 488 for JA11 versus grey bar for GR14). Furthermore, the source functions do not have the same sensitivity to the choice of the larger aerosol size. Some source functions are very 490 sensitive to the radius of the coarser section, which leads to large changes in the mass 491 flux (SM98, MA06 and GR14) with larger mass emissions for bigger particle bins. But 492 for the others, the number flux for larger particles decreases fast which causes the mass 493 flux to increase less as radii increase. For the SSaer emissions, although it is critical for 494 the wind speed (and SST when used) to be accurately represented, the diversity between 495 models is driven primarily by the choice of the source function formulation and aerosol size bins rather than by meteorological differences (see Figure 6a and Figure 6b). When 497 changing wind speeds by $\pm 1 \,\mathrm{m \, s^{-1}}$ (which is the spread found in CMIP6 models), the 498 impact on the mass emission flux is generally smaller than a change in the coarse mode 499 aerosol size bins. Figure 6b also shows the influence of accounting for SST in the source 500 function (blue and green stars). In general, changing the SST by $\pm 5^{\circ}$ C leads to a sim-501 ilar to smaller change in the mass emission flux than varying the wind speed by $\pm 1 \,\mathrm{m \, s^{-1}}$. 502 Since the spread in SST in CMIP6 models is less than 5° C, we therefore conclude that 503 the emission flux dependence on SST is not an important contributor to the CMIP6 model diversity. 505

The fine aerosol size bins (taken here as 300 nm and smaller aerosol diameter) in-506 fluence the number of SSaer potentially acting as CCN. BCC-ESM barely produces any 507 SSaer below 300 nm since the smaller aerosol bin considered has a minimum diameter 508 of 200 nm. For the other source functions, we compute the number emission flux con-509 sidering the following SSaer diameter bins: [30-40-50-60-70-80-90-100-200-300] nm. In 510 this range of diameters, the total number flux of SSaer varies by a factor of 8, except for 511 the MO86 function which yields a number flux 2 orders of magnitude larger in this size 512 range. Therefore, for models including the interactions of aerosols with radiation and clouds, 513 the choice of source function can strongly influence the associated radiative impacts, as 514 illustrated in Prank et al. (2022). 515

In summary, the large variety in the magnitude of simulated SSaer concentrations 516 at the poles is driven primarily by the choice of aerosol emission sizes and the source func-517 tion, and secondly by the meteorological drivers of emissions (open ocean fraction, wind 518 speed, mean planetary boundary layer height). The atmospheric processes (deposition, 519 transport, ageing) and thereby the residence time of SSaer drives the differences in spa-520 tial distribution and concentrations over the ocean and land. The variety in seasonal-521 ity is primarily driven by sea ice and meteorology, with diverse sea ice concentration and 522 wind speed annual cycles modulating emissions, but also heterogeneity in the represen-523 tation of the planetary boundary layer and deposition which influence concentrations ir-524 respective of the emission flux. The choice of aerosol sizes and source function formu-525 lation also affects the number of SSaer that could act as CCN. 526

527

3.2 Evaluation using observations

528 3.2.1 Comparison with ground based stations

Given the previously identified diversity in *mmrss* in the investigated CMIP6 models, a comparison with the observed sodium aerosol concentration from ground-based stations is conducted to evaluate individual model and ensemble performance (Figure 7, Fig⁵³² ure 8 and Figure A2). Figure 7 summarizes the comparison between the annual cycle
⁵³³ of sodium near-surface concentration in the CMIP6 models and the measurements for
⁵³⁴ the 14 stations. The NMB and correlation of the annual cycle of individual models as
⁵³⁵ well as the ensemble mean are computed. Reanalysis data from MERRA2 and CAMS
⁵³⁶ are also included. The data from observations and models are averaged over the longest
⁵³⁷ available period for each of them, i.e. 1951–2014 for CMIP6, 1980–2021 for MERRA2,
⁵³⁸ 2003–2021 for CAMS, and as indicated in Figure 1 for the measurements.

539 Arctic

For the Arctic stations, Figure 7 shows that most CMIP6 models have mean con-540 centrations around two to eight times larger than observations. Except for one station 541 where it is negative, the correlation between the modeled and observed annual cycles of 542 concentrations are positive, and mostly above 0.5, indicating a reasonable seasonality. 543 At the Irafoss and Summit stations, the correlation coefficient between the CMIP6 en-544 semble mean annual cycle and the observations is high, at 0.85 and 0.84, respectively, 545 despite NMB of up to one order of magnitude in individual models. At the Zeppelin, Utqiagvik, 546 Pallas, Karasjok and Bredkälen stations, NMB and correlations are between 91% and 547 435%, and 0.61 and 0.81, respectively. Unlike the two previous ones, some models at these 548 four stations are not significantly correlated with the observations at the 95% level. Alert 549 and Villum stations are the only two locations where the NMB is relatively small, and 550 negative (around -20%). However, due to the low correlation (-0.45 at Alert, 0.44 at Vil-551 lum), this relatively low NMB is not a sign of good performance, as discussed later. 552

In order to understand if the variation by season for SSaer is correctly represented 553 we apply a bias correction on CMIP6 model output (Figure 8). For each model, the an-554 nual cycle is adjusted by the factor OBS_{i}/OBS_{i} , which is the annual mean observed 555 sodium concentration divided by the annual mean in the model for each station. Using 556 the bias corrected data (Figure 8) for the Arctic stations Alert and Villum, CMIP6 mod-557 els have very diverse annual cycles (the median correlation across models is not signif-558 icant at the 90% level). The ensemble mean has no significant correlation with the cor-559 responding observations at the 95% level (boundaries of the confidence interval have op-560 posite signs). Also, the yearly maximum in Aug–Sep in the models contrasts with ob-561 servations which are at their minimum during that period. For such high-latitude sta-562 tions, where the Arctic Ocean is covered with sea ice throughout the year and the pro-563 duction of sea spray does not occur, it is thought that the observed wintertime SSaer max-564 imum originates from blowing snow on sea ice emissions (Yang et al., 2008; J. Huang & 565 Jaeglé, 2017; Yang et al., 2019) or from sea spray originating from leads (Held et al., 2011; 566 Kirpes et al., 2019). In CMIP6 models, these sources are not included in the parame-567 terizations, which may explain the lack of correlation with observations at Alert and Villum and the negative NMB in wintertime. However, some models (UKESM and HadGEM) 569 seem to have the right seasonal cycle at Alert, without including a sea ice source of SSaer. 570 Additional analyses show that the emissions surrounding the location have a minimum 571 in winter, but the annual cycle of planetary boundary layer height varies more with sea-572 son in UKESM and HadGEM compared to the other models, with higher values in sum-573 mer and shallower heights in winter (see Figure A3). This explains the shape of the an-574 nual cycle despite the absence of winter local sources in the models. Since winter sources 575 such as blowing snow are observed in measurements (Frey et al., 2020), these two mod-576 els likely have the right annual cycle for the wrong reasons. Except at Utqiagvik where 577 the Dec–Jan high concentrations are missed by the models, the seasonality is reasonably 578 well captured by the ensemble mean at the other locations. 579

580 Antarctic

For Antarctic stations, the magnitudes of the NMB are similar to those of the Arctic sites, except at Dumont d'Urville and Neumayer where several models have a relative NMB below 100% (Figure 7). The diversity between models is large as well, with
no significant across-model correlation at the 90% level for any station, and a strictly
positive correlation at the 95% level of the ensemble mean with observations only at Dumont d'Urville and Palmer stations (Figure 8). At Concordia station, two models exhibit an Arctic-like cycle with maximum concentrations in Dec–Feb (MRI-ESM and MIROCES2L), while the others produce an annual cycle with maximum concentrations in Jun–
Aug. In both groups, the clear maximum recorded by measurements in November is missed.

The models are relatively good at the coastal site of Dumont d'Urville, with a 0.64 590 591 correlation and a bias corrected annual cycle mostly within one standard deviation of the observations (Figure 8). In contrast, at Concordia station which is 1200 km further 592 inland from Dumont d'Urville (Figure 1), the correlation with observations is not sig-593 nificant at the 95% level and not one individual model is within one standard deviation 594 of the measurements. This difference in performance might be indicative of inadequate 595 removal processes over land. In particular, climate models at a resolution lower than 1° 596 tend to underestimate precipitation over Antarctica (Tang et al., 2018), which would re-597 sult in too low wet deposition along transport, and therefore too high concentrations over 598 the continent, despite reasonable concentrations at the coast. In addition, the orogra-599 phy of this region might not be well reproduced in climate models, which could lead to 600 inadequate dynamics and thus explain the shortcomings in CMIP6 in terms of the an-601 nual cycle of SSaer. 602

At Halley station, the comparison is partially hindered by the relatively short length 603 of the observation records, which only cover 3 years and comprise a large variability, but 604 the CMIP6 bias-corrected values are mostly within one standard deviation of the obser-605 vations for this station (Figure 8). At Neumayer station, the shape of the annual cycle 606 in the models is reasonable but is shifted two months too early compared to measure-607 ments. At Dumont d'Urville, all models adequately produce a maximum in Dec-Feb, al-608 though generally too high compared to observations and possibly one month late, which 609 leads to a distorted seasonal cycle. A similar comparison can be made for Palmer sta-610 tion, although with a maximum delayed by two months compared to Dumont d'Urville. 611 These two latter stations are the lower latitude ones (north of 70° S) where the sea ice 612 maximum extent in winter is lower according to Figure 1. Like for the Arctic, the ab-613 sence of a sea ice related SSaer source in the models (blowing snow, leads) degrades their 614 performance during winter. 615

Reanalyses

616

Two reanalysis data sets are also included in this analysis (Figure 7) and compared 617 to observations. MERRA2 is known to have a positive bias on SSaer mass concentra-618 tion of around one order of magnitude even at lower latitudes (Kramer et al., 2020), which 619 was partly attributed to a distortion of the size distribution of SSaer, with too few small 620 particles and too many large ones (Bian et al., 2019). This is consistent with Figure 7 621 where MERRA2 is found to systematically overestimate concentrations with a larger pos-622 itive NMB than the CMIP6 ensemble mean, for both poles, between 163% and 2,532%. 623 CAMS has a generally better performance than MERRA2, both in terms of correlation 624 and NMB, the latter being limited to 730% at most. Generally speaking, CAMS is less 625 biased than the CMIP6 ensemble, but has a lower correlation when it comes to repro-626 ducing the observed annual cycle. These two comparisons show that despite being com-627 monly used as validation data sets, reanalyses have difficulties in reproducing observed 628 SSaer concentrations at the poles, and have a generally poorer performance than the CMIP6 629 ensemble. However, since SSaer concentrations are not assimilated in these reanalyses, 630 and AOD is assimilated only as total AOD, a better performance than CMIP6 was not 631 expected. 632

3.2.2 Comparison of modeled SSaer AOD with MODIS AODss

633

AOD is often used to evaluate aerosols in climate models, since it is closely related 634 to the full aerosol burden throughout the atmospheric column, including the impact of 635 water uptake on aerosols. It is also more closely related to direct aerosol-radiation cli-636 mate forcing than surface observations, and is less sensitive to errors in vertical aerosol 637 distributions. SSaer AOD at 550 nm is provided for a subset of CMIP6 models includ-638 ing BCC-ESM, EC-Earth, IPSL-CM6, MPI-ESM, MRI-ESM, NorESM, and compared 639 here to AODss at 550 nm extracted from MODIS Dark Target/Deep Blue satellite data 640 (Figure 9). The monthly MODIS data are processed as described in Section 2.2.2 to ap-641 proximate the contribution of SSaer to total AOD, noting that AOD is not available for 642 cloud covered regions and ice/snow covered surfaces. MODIS data is also scarce during 643 the polar night due to the absence of visible light. MODIS Terra and MODIS Aqua AODss 644 are shown separately due to the differences between these two monthly AOD products 645 (Sogacheva et al., 2020). 646

Figure 9 shows the magnitudes and spatial patterns of SSaer AOD in CMIP6 and 647 AODs in MODIS, for the Arctic and the Southern Ocean. In the northern Atlantic, the 648 CMIP6 ensemble median is around 0.02 (0.04, respectively) higher than MODIS Terra 649 (Aqua, respectively). Spurious high AODss values in satellite data over the high Arc-650 tic (brown pixels in Figure 9 middle with AODss up to 1 on average) could be artifacts 651 related to the scarcity of valid records available in the region (due to possible cloud con-652 tamination or poor snow/sea ice screening) making the comparison more difficult. For 653 the Antarctic, values south of 60°S are comparable between CMIP6 SSaer AOD and MODIS 654 AODs, below 0.02 in coastal regions with a positive northward gradient up to around 655 0.08 at 60° S. However, in the area between 50° S and 60° S, the band of maximum SSaer 656 AOD in CMIP6 is not observed in the AODs MODIS data (Terra or Aqua), except for 657 sporadic hot spots. For this area, the spatial distribution in MODIS is less homogeneous 658 and has a lower AODss on average compared to CMIP6. Given the semi-permanent pres-659 ence of clouds at these latitudes, around 90% annually (Lachlan-Cope, 2010), a sampling 660 bias in the MODIS data cannot be excluded to account for this discrepancy, which does 661 not invalidate the high values in CMIP6. 662

The spatially averaged SSaer AOD and AODss show reasonable agreement between 663 CMIP6 and MODIS in terms of the annual cycle (Figure 9 right). For the Arctic, MODIS 664 features a late winter (Feb-Mar) maximum in AODss that is not represented in the models, whereas most models have a maximum SSaer AOD in early winter (Dec–Jan) that 666 is not found in MODIS and up to 0.1 higher than the MODIS values. However, for those 667 winter months (Nov–Feb), the MODIS data are more sparse than in summer (Jun–Sep), 668 which could result in another sampling bias (Figure 9 right - grey bars). Since cloud cover 669 is lower in winter compared to summer (Eastman & Warren, 2010), and should there-670 fore impede AOD retrieval less often, sea ice cover can explain the lack of records, in com-671 bination with the polar night. Sea ice is at its maximum extent and is too bright a sur-672 face for MODIS instruments to accurately separate the contribution to back-scattering 673 from the ground and from aerosols (Mei et al., 2013), leading to fewer valid records in 674 winter than in summer. On the other hand, the MODIS-derived annual cycle of AODss 675 is quite similar to the cycle of total aerosol mass and surface area observed in Tunved 676 et al. (2013), which could indicate limitations in our AODss extraction approach. Sim-677 ilarly, the scarcity of MODIS data in the Antarctic for Mar–Sep prevents such a com-678 parison. Furthermore, the observed decrease in AODss in Apr–May could be due to a 679 sampling bias, since MODIS records are less numerous south of 60° S compared to other months (Figure 9 - grey bars). For the austral summer months (Nov–Feb), when the com-681 parison is less uncertain due to a larger number of available records, all the models are 682 within one standard deviation of both MODIS Terra and Aqua values and closer to the 683 Aqua mean. This is true for all the models in the Arctic, and most of them in the Antarc-684

tic. The shape of the monthly variations is reasonably well reproduced in both cases, except in winter.

The CMIP6 ensemble is closer to MODIS Terra when it comes to climatological 687 maps, but closer to MODIS Aqua for the summer months, when the comparison is more 688 robust thanks to a larger number of MODIS records. The offset of around 0.02 obtained 689 here between MODIS Aqua and MODIS Terra in our AODss product is well known and 690 described in the literature, in which MODIS Aqua is considered to be more accurate than 691 MODIS Terra (Sogacheva et al., 2020). Therefore, the better agreement of CMIP6 mod-692 els with MODIS Aqua in summer is an indication that the SSaer AOD is reasonably cap-693 tured in the CMIP6 models, although the model variability is large for the winter months. 694

Despite the fairly large discrepancies in mmrss revealed in Section 3.2.1, the SSaer 695 AOD at 550 nm shows better performance in the CMIP6 models compared to the satel-696 lite data. This indicates that the direct radiative effect of SSaer is likely well reproduced for the poles as well. This also suggests, given the bias on surface mass concentrations, 698 that (i) the size distribution of SSaer might not be adequate, possibly steered toward too 699 coarse particles, or (ii) that the vertical distribution of SSaer is biased and accumulates 700 too much mass at the surface. However, the good performance in SSaer AOD is not nec-701 essarily a sign of adequate fine mode number concentrations. Some models are known 702 to have hygroscopic growth factors that are too high (Burgos et al., 2020), which can in-703 crease SSaer AOD despite incorrect (too low) quantities of fine fraction mode particles. 704 Although this is not analyzed further in this work, compensating effects between num-705 ber, size and hygroscopicity of SSaer needs further investigation in the future. 706

707

3.3 Implications for our understanding of polar climate

In this section we address the implications of the diverse representation of SSaer in CMIP6 for our understanding of present and future climate. In what follows, we first evaluate the sensitivity of the polar climate to SSaer based on the CMIP6 *piClim*-2xss experiment. Then, historical and future trends of SSaer emissions and *mmrss* are investigated under scenarios SSP126 and SSP585 to assess the uncertainty borne by climate projections owing to SSaer.

714

3.3.1 Radiative impact of SSaer

The pre-industrial climate experiments from the AerChemMIP activity provide a 715 control (piClim-control) and a doubled SSaer emission (piClim-2xs) experiment, for a 716 30 year period under 1850 climate conditions. Three CMIP6 models provide the top-of-717 the atmosphere net downward radiative flux (rtmt) for these experiments and are used 718 in this section. The change in rtmt between the 2xss and *control* experiments is used 719 here to evaluate the radiative impact of SSaer. The entire 30 year period is considered. 720 For the three models considered, this includes the aerosol-radiation interaction and the 721 aerosol-cloud interaction, although they cannot be disentangled, since *rtmt* provides to-722 tal radiation only (short-wave + long-wave). The piClim simulations are fixed-sst, so that 723 rtmt includes the effect of rapid atmospheric adjustments, but not the effect of climate 724 feedbacks from long-term surface temperature change. In this respect, the *rtmt* change 725 is comparable to an effective radiative forcing. 726

One important factor for the direct and indirect radiative effects of SSaer is their vertical distribution. We show the diversity in the vertical distribution of both SSaer and clouds in Figure A4 for ocean/ice covered regions north/south of 60°N/S. There is a large diversity between modeled profiles, of more than two orders of magnitude above 5,000 m altitude for SSaer, and a factor of around 10 in clouds throughout the column. This suggests that the radiative impact of SSaer can also be assumed to be very diverse and uncertain.

Figure 10 shows the average change in rtmt between the doubled SSaer emissions 734 and the control experiment, for summer months and winter months in the Arctic and 735 Antarctic. In summer, when sea ice extent is at its minimum in the Antarctic, the ra-736 diative impact of SSaer is mostly negative (cooling effect) in the three models over the 737 ocean, with up to $-10 \,\mathrm{W\,m^{-2}}$ in NorESM and $-5 \,\mathrm{W\,m^{-2}}$ in IPSL-CM6 and UKESM (Fig-738 ure 10). This important change is probably partly related to the aerosol-cloud interac-739 tion and its albedo effect over darker surfaces (open ocean), as found in Struthers et al. 740 (2011). The aerosol direct effect also likely contributes to this change, especially in NorESM 741 where the change in AOD is large over the Southern Ocean, with more than +0.25 on 742 average (Figure A5). Such an important change is not found in the other models for the 743 Southern Ocean (less than +0.1), explaining why the cooling effect is larger in NorESM 744 in summer in the Antarctic than in IPSL-CM6 and UKESM. 745

Over the Antarctic continent in summer, for most areas the radiative impact can-746 not be significantly distinguished from zero at the 90% level according to a Wilcoxon test, 747 but regionally averaged south of 60° S, a negative radiative impact significant at the 95% 748 level is found, comprised between -0.34 ± 0.02 W m⁻² and -1.01 ± 0.07 W m⁻² (Table 2). 749 In winter, when sea ice extent is larger and there are fewer areas prone to sea spray pro-750 duction in the region, the radiative impact is slightly positive in West Antarctica but mostly 751 not significantly different from zero at the 90% level in the region when considering all 752 three models (Figure 10 and Table 2). 753

NorESM and UKESM indicate a cooling effect in the high Arctic in winter, with 754 a regionally significant negative radiative impact at the 95% level (Table2). IPSL-CM6 755 suggests a small heating effect in northeastern Canada and a slight heating in the high 756 Arctic for Dec–Feb, although the regional average is smaller than the cooling obtained 757 in the other models. In summer, the changes are stronger and more heterogeneous, with 758 regions of large cooling next to regions of large heating, although generally not signif-759 icant at the 90% level (Figure 10), resulting in a regionally weak cooling effect overall 760 in all the models (Table 2). The weak change in AOD in summer can partially explain 761 this moderate radiative effect (Figure A5). 762

The effects of doubling SSaer can be further described in terms of changes in air 763 surface temperature (tas variable in CMIP6), as shown in Figure A6. NorESM predicts 764 a warming in the winter both in the Arctic and Antarctic $(+0.20^{\circ}C \text{ and } +0.17^{\circ}C, \text{ re-}$ 765 spectively), while the response in the other models is either a slight cooling or warming, 766 but one order of magnitude smaller. In the summer, models agree on a cooling effect in 767 the Arctic $(-0.013^{\circ}\text{C to } -0.078^{\circ}\text{C})$, while the sign of the change is uncertain in the Antarc-768 tic (the average of the three models shows a zero net change). In the winter, these changes 769 in temperature are equally driven by oceanic and land regions, whereas in the summer 770 the temperature change is mainly found above land. This may be related to the more 771 homogeneous surface albedo in winter when sea ice extent is large and land is covered 772 in snow, whereas in summer the heat capacity of the open ocean contrasts with that of 773 the land. These changes in surface temperature are not directly connected to the changes 774 in top-of-the-atmosphere radiation found in Table 2, particularly in the Antarctic where 775 the large summer decrease in radiation in NorESM $(-1.01 \,\mathrm{W m^{-2}})$ yields a surface warm-776 ing of $+0.065^{\circ}$ C. Cooling/heating effects over land/ocean which have different heat ca-777 pacity and albedo may be at play in this case. The vertical distribution of the changes 778 in radiation may also play a role. 779

Figure A6 also shows the same change in surface temperature but in the *piClim*-781 2x*dust* experiment, where dust emissions are doubled, instead of SSaer. In the Antarc-782 tic, both species have similar impacts on surface air temperature (very limited in sum-783 mer months, slight warming in winter months, on average). In the Arctic, dust have a 784 cooling effect in winter, of the same magnitude as the warming induced by SSaer, whereas 785 in summer, the cooling from SSaer is one order of magnitude larger than the cooling from 786 dust. The changes are also more widespread around zero in the case of SSaer, with wider distributions than for dust, suggesting a greater sensitivity to SSaer than dust. Compared to SSaer, dust has limited local sources at the poles and mostly comes from longrange transport, which explains its smaller regional impact. However, this comparison
speaks to the relevance of evaluating more closely SSaer and their climate impacts at the
poles, which are comparatively less studied than for dust.

The implications of the previous analyses are not straightforward, since the piClim792 experiments consider pre-industrial atmospheric conditions, free of the current anthro-793 pogenic background. Although polar regions remain relatively pristine areas, they are affected by the transport of anthropogenic emissions from lower latitudes through warm 795 air mass intrusions (Li & Barrie, 1993; Quinn et al., 2002; Dada et al., 2022). The non-796 linearity of aerosol-cloud interactions (Gryspeerdt et al., 2019) requires an adequate aerosol 797 background, including anthropogenic sources, to obtain reasonable estimates of the in-798 direct effect of SSaer emissions and therefore its radiative impact. Furthermore, the ra-799 diative impact depends not only on the proper representation of the number and sizes 800 of SSaer, but also on their hygroscopicity, particularly for the direct effect (Zieger et al., 801 2017), which are quite uncertain according to Section 3.1. 802

The relatively strong effect on radiation of doubled SSaer emissions puts Figures 2, 803 3 and 5 into perspective: the difference in SSaer emissions between two models can be 804 up to a factor of 4, which according to Figure 10 should mean that the resulting radia-805 tive budget at the poles could differ by up to $2 \,\mathrm{W}\,\mathrm{m}^{-2}$ (depending on the season and the 806 model). This suggests that the uncertainty on the polar radiative budget related to SSaer 807 within CMIP6 models could have the same magnitude as the 20th century increase in 808 global radiative forcing (Myhre et al., 2013). These numbers are in line with those from 809 Struthers et al. (2011), where a 23% increase in SSaer AOD in the Arctic is estimated 810 to result in a -0.2 to -0.4 W m⁻² radiative impact. 811

812

3.3.2 Historical and future trends

As a result of polar amplification, the polar climate is changing even more dramat-813 ically than the global climate. Given the connection of sea spray emissions with sea ice 814 and atmospheric dynamics (e.g. wind speed), significant trends can be anticipated in SSaer 815 both in present day and future scenarios. These are investigated using ScenarioMIP ex-816 periments SSP126 and SSP585 (O'Neill et al., 2016). The analysis conducted hereafter 817 is restricted to the six CMIP6 models that provide *mmrss* in both scenarios, namely GISS, 818 HadGEM, MIROC-ES2L, MRI-ESM, NorESM and UKESM. We note that observations 819 do not have long enough time series to compute multidecadal trends for validation pur-820 poses. 821

In the historical period 1951–2014, the mass emission flux of SSaer in the polar re-822 gions generally increased and comparatively more homogeneously in the Southern Ocean 823 than in the Arctic (Figure 11 top). In the latter region, emissions increased more strongly 824 in the Barents Sea and Greenland Sea, at a rate of up to +6% per decade. In the high 825 Arctic, this trend is lower, between +1.5% and +3% per decade, with no trend between 826 -60°E and -180°E. In the Southern Ocean the increasing trend is more homogeneous, be-827 tween +1.5 and +6% per decade in most of the area. For the Arctic and Antarctic, the 828 historical trend is mainly driven by sea ice retreat, although a slight increase in wind speed 829 is also found in the Antarctic (Figure A7). This Antarctic increase in SSaer is consis-830 tent with the findings of Korhonen et al. (2010). To some extent, the difference in trends 831 of wind speed between the Arctic and Antarctic might be related to an asymmetry in 832 the trends and dynamics of stratospheric ozone depletion (Turner et al., 2009). 833

Future scenarios in CMIP6 follow the Shared Socioeconomic Pathway (SSP) trajectories (O'Neill et al., 2016). Here, we consider the two extreme scenarios, SSP126 and SSP585. SSP126 represents the low end of the range of plausible future pathways, where radiative forcing reaches a level of approximately 2.6 W m⁻² in 2100 compared to the pre-

industrial period. SSP585 is at the other end of the spectrum, with a radiative forcing 838 of approximately $8.5 \,\mathrm{Wm}^{-2}$ at the end of the century. In both of these scenarios, the 839 Arctic surface air temperature warms more than the global mean. The change in tem-840 perature between 2000–2014 and 2085–2100 is different by a factor of around 2 between 841 the global and Arctic average $(3.8^{\circ}C \text{ versus } 1.5^{\circ}C \text{ in SSP126 and } 10.8^{\circ}C \text{ versus } 5.1^{\circ}C$ 842 in SSP585, respectively), and with a large uncertainty (model spread of 7° C in SSP126 843 and 10°C in SSP585). In contrast, the Antarctic has a lower warming than the global 844 mean in both scenarios (Table A1). 845

846 The spatially averaged time series of the yearly surface mmrss (Figure 11) show different behaviors between the two poles over the historical period and in the two fu-847 ture scenarios SSP126 and SSP585. In the Arctic, in scenario SSP585, each individual 848 model features an increasing trend resulting in the multiplication of surface *mmrss* by 849 a factor of 1.75 to 2.8 in 2099 compared to the 1951–1971 average (hereafter referred to 850 as baseline). In the ensemble mean, this increase is by a factor of 2.2. In the SSP126 sce-851 nario, three models show a stabilization after 2050 and a slight decrease at the end of 852 the century. The two remaining models feature a stronger increase, lasting until the end 853 of the century and reaching levels comparable to those obtained in some models in SSP585. 854 The associated ensemble mean stabilizes at just under a 1.5 increase at mid-century com-855 pared to the baseline. These trends mirror the trends in Arctic sea ice in the CMIP6 mod-856 els analyzed in Notz and SIMIP Community (2020), showing decreasing sea ice cover un-857 til 2050, followed by a stabilization in SSP126 and a continuous decrease until the end 858 of the century in SSP585. As a result, differences in trends in individual models might 859 come from differences in their underlying sea ice evolution. In the Antarctic, the SSP585 860 trajectory is similar to that in the Arctic, except for a smoother increase, by no more 861 than a factor of 2 in the more extreme model. Contrary to the Arctic, the increasing trend 862 in mmrss starts in the 1980s, and the SSP126 and SSP585 trajectories start separating 863 only around the year 2030, after which mmrss reaches a plateau in SSP126 until the end 864 of the century. For both poles, NorESM, which is the only model in this analysis that 865 includes an SST dependence in its sea spray source function, and which is not based on 866 a whitecap approach, shows the smallest increase in concentration at the end of the cen-867 tury, in SSP126 and SSP585. This is consistent with Figure 6 which showed that for in-868 creased SST, the SSaer mass flux decreases in the SA15 source function. As a result, in 869 a warming climate, accounting for the increase in SST decreases the SSaer mass flux at 870 the poles compared to not accounting for it. Generally speaking, the trends in all the 871 models are marginally larger in winter than in summer. For comparison, mid-latitude 872 oceans do not show historical or future trends in *mmrss*. 873

In addition to following different trajectories, future trends in surface *mmrss* in the 874 Arctic and Antarctic also have a different spatial distribution, although in both cases a 875 slight negative trend is found over land in Greenland and the Antarctic continent (Fig-876 ure A8). This negative trend over land can be explained by increasing precipitation, and 877 therefore decreased aerosol residence time, in SSP scenarios in the Arctic (McCrystall 878 et al., 2021) and over Antarctica (Tewari et al., 2022). All of the Arctic Ocean where sea 879 ice can currently be found features a strong decreasing trend in sea ice concentration (Fig-880 ure A8), which explains the strong increasing trend in *mmrss* in scenario SSP585. In con-881 trast, the trend in the Antarctic is mainly driven by increasing *mmrss* in the Belling-882 shausen Sea, and marginally by localized spots in the Wedell Sea, which appear to be 883 sea ice driven (Figure A8). 884

A multiplication of SSaer mass emissions in the Arctic by 3 in SSP585 (as indicated by the CMIP6 ensemble mean) could imply a regionally negative radiative impact of around -1 W m^{-2} to -2 W m^{-2} in winter at the end of the century based on Section 3.3.1 (see Figure 10 and Table 2). In particular, UKESM that showed a high sensitivity to doubled SSaer emissions (Table 2) is also the model with the largest future trends in scenario SSP585. The limited emission trend in the Antarctic, including in SSP585, suggests a smaller counteracting effect of SSaer on polar warming. Nevertheless, these changes in mass emissions do not necessarily translate into a similar change in number of SSaer, and the latter can have a large impact on the indirect effect of SSaer. No information on the change in number of aerosols is available in CMIP6 models to further investigate these future trends in radiative effect, making them quite uncertain.

4 Conclusions and Perspectives

This work evaluates the representation of SSaer in polar regions within CMIP6 including a comparison to surface station observations and satellite AOD. Implications for the radiative balance at the poles in the present-day and future climate are also investigated. We address the questions:

How diverse are SSaer emissions/concentrations at the poles in CMIP6 models? 901 The inter-model comparisons result in the same conclusions for the Arctic and Antarc-902 tic, with a large diversity (up to a factor of 5) in the magnitude of simulated surface mass 903 concentration of SSaer. The spatial distribution is generally consistent between models 904 although the amount of SSaer transported over land varies. Diversity is also important 905 in emissions (factor 3), aerosol layer height (factor 7-8), lifetime (factor 9), optical depth 906 (factor 4) and total deposition (factor 2-3), resulting in a generally uncertain SSaer bud-907 get at the poles in CMIP6. 908

What are the drivers of this model diversity The model diversity in CMIP6 is driven 909 by differences in the sea spray source function formulations and by the drivers of sea spray 910 emission (wind speed, sea-ice cover). We also show large differences in residence time which 911 affect the transport of SSaer and are responsible for model diversity over land. Other 912 SSaer related variables such as AOD, aerosol layer height and deposition fluxes are also 913 diversely represented. We show that even if the emissions were identical, the surface mix-914 ing ratio of SSaer would still be different due to different treatments of boundary layer 915 dynamics, aerosol models (micro-physics, treatment internal/external mixing, hygroscop-916 icity, size bins/modes), and deposition fluxes of the SSaer. 917

How well do the CMIP6 models represent SSaer at the poles relative to surface ob-918 servations and remote sensing? The evaluation of the modeled surface concentrations 919 of sodium mass against ground station observations shows there is a large positive bias 920 of up to one order of magnitude in CMIP6 models. Once the mean bias is corrected, the 921 seasonal variations of SSaer concentration are relatively well captured for lower-latitude 922 stations. For high-latitude stations, there is a deformation of the annual cycle in mod-923 els compared to observations. The absence of wintertime local sources of SSaer such as 924 blowing snow over sea ice and emissions from open leads can be one reason for that. Pos-925 sible biases in sea ice representation could also be responsible. Models that include a SST 926 dependence in the SSAer source function are not less biased than ones that do not, be-927 cause the effect of SST change is smaller than other sources of bias from source functions, 928 meteorological drivers, and aerosol processing. Modeled SSaer AOD compares well with 929 satellite data, potentially indicating that improvements could be made to the size dis-930 tributions to overcome the discrepancy in concentrations, assuming that the hygroscop-931 icity factor is adequately represented. 932

What are the implications of model diversity and changes in SSaer emissions, for 933 the present and future polar climate? Pre-industrial and future climate CMIP6 exper-934 iments show that models agree that a doubling of SSaer emissions exerts a net negative 935 radiative perturbation at the top of the atmosphere in summer in the Arctic and the Antarc-936 tic, with less agreement for the sign of the impact in winter. In terms of surface temper-937 ature, models agree on a cooling effect in summer in the Arctic but disagree on the sign 938 of the change for winter and for the Antarctic. These impacts are generally heteroge-030 neous in terms of their spatial distribution, but the large uncertainty in the present-day 940

emissions shown here means possibly an uncertainty of up to 2 W m^{-2} in the polar radiative budget. A multiplication of SSaer mass emissions in the Arctic by more than 2 in SSP585 (as indicated by the CMIP6 ensemble mean) could imply a regionally negative radiative impact around -1 W m^{-2} in winter at the end of the century.

These conclusions highlight the need for additional research on the representation of SSaer at the poles. In particular, polar-specific source functions and size distribution could help improve the simulated concentrations according to our findings. Additionally, this work shows that aerosol-radiation and aerosol-cloud interactions of SSaer at the poles cannot be ignored in models and need to be activated and accurately represented to obtain a reliable radiative budget, including to quantify anthropogenic aerosol radiative effects.

Figure 1. Arctic and Antarctic measurement stations providing sea salt surface mass concentration data. Blue colormaps indicate areas with a sea ice concentration above 50%. The lighter blue is for February in the Arctic, and August in the Antarctic. The darker blue is the opposite. The sea ice data are from ERA5. The black dashed line shows the 60° limit considered for regional aggregated analyses. Abbreviations in the maps are the first two letters of the corresponding station name.

Figure 2. Sea salt aerosol mass mixing ratio in the lowest model level. Annual average for the period 1951–2014 in the CMIP6 historical scenario. Arctic map. NB: CNRM-ESM values are divided by 25 to fit in the colorbar.

Figure 3. Same as Figure 2 but for the Antarctic.

Figure 4. Model diversity in mass emissions, surface mass mixing ratio, aerosol layer height, AOD, dry and wet deposition, and lifetime of sea salt aerosol. Average for the period 1951–2014. The color scale highlights the highest values for each column. CNRM-ESM is excluded from this color scale for mass emission and *mmrss*. Empty cells indicate that values are not provided by the model. *mmrss* is multiplied by 10 and AOD is multiplied by 1000 for improved readability.

Figure 5. Annual cycles of sea salt aerosol mass mixing ratio at surface level (a,b), sea salt aerosol mass emission (c,d), fraction of open ocean (e,f), surface wind speed (g,h) and planetary boundary layer height (i,j) at latitudes above 60° N (left) and below 60° S (right) in CMIP6 models for the period 1951–2014. Lines show the monthly average over the period for each model. Emissions are summed to obtain the total emission flux over the considered region. Mixing ratio, wind speed and planetary boundary layer height are averaged for grid points over the ocean, with non-zero emissions and less than 90% sea ice cover. The open ocean fraction is computed as one minus the average of the sea ice concentration over the considered region. Panels (i,j) only include the 9 models providing the *bldep* variables (i.e. all except BCC-ESM, CNRM-ESM and MRI-ESM). Panels (c,d) do not include BCC-ESM as emission rates are not available for that model. CNRM-ESM is not included in this analysis.

Figure 6. Sea salt aerosol source functions used in CMIP6 models. a) effect on the mass emission flux of changing the aerosol cut-off radius, at 10 m s^{-1} wind speed and 5°C SST. b) effect of changing wind speed on the mass emission flux for a cut-off radius at 10 µm. Green and blue stars indicate mass emission fluxes for 0 and 10°C SST, respectively, at 10 m s^{-1} wind speed. In both panels, size bin limits are taken as 0.05-0.5-1- R_{max} µm.

Figure 7. Normalized mean bias (numbers, in percent) and Pearson correlation coefficient (colormap) with respect to 9 stations in the Arctic (in black) and 5 stations in the Antarctic (in blue). CMIP6 individual models and ensemble mean are for the period 1951–2014, CAMS reanalysis is for 2003–2021 and MERRA2 is for 1980–2021. See Figures 8 and A2 for individual comparisons of time series.

Figure 8. Annual cycle of sodium aerosol surface mass concentrations at 9 stations in the Arctic (top and middle) and 5 stations in the Antarctic (bottom). Observations are in black (caps show one standard deviation of monthly means), individual CMIP6 models (1951–2014) are in light blue, CMIP6 ensemble mean (solid thick line) is in blue. CMIP6 values are bias corrected by applying a factor $iOBS_{i}/iMODEL_{i}$. Boxes indicate the Pearson correlation coefficient between the annual cycle in CMIP6 ensemble mean and observations, with the 95% confidence interval between brackets.

Figure 9. CMIP6 ensemble median and MODIS Terra (MOD08_M3) and Aqua (MYD08_M3) Dark Target/Deep Blue sea salt aerosol optical depth at 550 nm. Both MODIS data sets and CMIP6 model data are averages of monthly means for the period 2005–2014. The CMIP6 ensemble contains a subset of models providing the *od550ss* variable (BCC-ESM, EC-Earth, IPSL-CM6, MPI-ESM, MRI-ESM, NorESM). MODIS values are adjusted to only account for the contribution to AOD of particles with Angstrom exponent below 1. Right: average annual cycles of sea salt aerosol optical depth in MODIS (Terra in black, Aqua in grey - caps show one standard deviation) and CMIP6 models (orange). MODIS and CMIP6 values are colocated, i.e. CMIP6 values are used only for those grid cells where MODIS has valid records. Gray bars indicate, on an arbitrary scale common to both panels, the number of available records in MODIS Terra.

Figure 10. Change in top-of-the-atmosphere net downward radiative flux (rtmt) in a scenario with doubled sea salt aerosol emissions under pre-industrial atmospheric composition (30 years under 1850 conditions). Stippling shows the grid points for which the difference between *piClim*-2xss and *piClim-control* is not significant at the 90% level according to a Wilcoxon test.

Historical trend in sea-salt aerosol mass emission flux

Historical and future trend in sea salt aerosol mass mixing ratio

Figure 11. Top: trends in sea salt aerosol mass emissions in the ensemble mean for the period 1951–2014. The mass emission is normalized by the 1951–2014 average to obtain %/decade. Bottom: historical and future (relative to the 1951–1971 mean) yearly time series (1951–2099) of average sea salt surface mass mixing ratio north of 60°N (left) and south of 60°S (right), including ocean and land. Mixing ratios are weighted by grid cell area for spatial averaging. Time series are smoothed using a Savitzky-Golay filter with a window length of 19 years and a polynomial order 3. Ensemble means are shown as thicker lines (black for the historical period, blue for SSP126, red for SSP585). Individual members use the same color code but with thinner lines. Included models are: GISS, HadGEM, MIROC-ES2L, MRI-ESM, NorESM and UKESM. The smallest (largest, respectively) trend in SSP585 corresponds to NorESM (UKESM, respectively).

954 Appendix A

Table A1. Regionally averaged mean change in surface temperature (*tas* variable - $^{\circ}$ C) in the CMIP6 ensemble of models GISS, HadGEM, MIROC-ES2L, MRI-ESM, NorESM and UKESM. This change is computed as the difference between the 2000–2014 historical and 2085–2100 future averages. Arctic is all grid points north of 60°N, Antarctic is all grid points south of 60°S. Spread here refers to the difference between the model with largest increase and the model with smallest increase.

	Glo	obal	Are	ctic	Antarctic		
	Mean	Spread	Mean	Spread	Mean	Spread	
SSP126	1.5	2.0	3.8	7.4	1.0	1.5	
SSP585	5.1	3.8	10.8	10.0	4.5	3.1	

A1 Sea salt dominance assessed from MACv2

955

Figure A1. AOD characteristics at the poles from the MACv2 climatology (Kinne, 2019). Left: fraction of coarse AOD (dust+sea salt) attributed to sea salt (annual average climatology). Only dust and sea salt are considered here since we look at the coarse fraction AOD. Middle: fraction of total AOD from fine mode aerosols. Right: total AOD.

-35-

A2 Non-normalized annual cycles versus observations

Figure A2. Annual cycle of sodium aerosol surface mass concentrations at 9 stations in the Arctic (top and middle) and 5 stations in the Antarctic (bottom). Observations are in black (caps show one standard deviation of monthly means), individual CMIP6 models (1951–2014) are in light blue, CMIP6 ensemble mean (solid line) and median (dashed line) is in darker blue, reanalyses (CAMS 2003–2021 - circles - and MERRA2 1980–2021 - triangles) are in brown.

A3 Annual cycles at Alert

Figure A3. Annual cycles of SSaer mass concentration (top - normalized), SSaer mass emission (middle - normalized) and boundary layer height (bottom) in CMIP6 at the grid point nearest to the Alert station. Average annual cycles for the period 1951–2014.

⁹⁵⁸ A4 Vertical distribution of SSaer and clouds

The evaluation conducted in Section 3.1 mainly focused on surface and column-959 integrated SSaer variables. To connect SSaer to clouds, information on the vertical dis-960 tribution is needed. Figure A4 shows the regionally averaged profiles of mmrss in the 961 Arctic and Antarctic in the historical period, in Jun-Aug and Dec-Feb. This figure shows 962 that the diversity at the surface affects also the vertical distribution. The inter-model 963 spread is roughly constant from the surface up to 400 m altitude and remains above $1 \,\mu g g^{-1}$ 964 at 10 km altitude in winter months. Given that SSaer are injected high enough to inter-965 966 act with clouds (Figure A4), part of the diversity in cloud profiles at the poles could stem from this diversity in SSaer profile. In summer months, the profiles converge more rapidly. 967

Figure A4. Left: Average vertical profile of sea salt aerosol mass mixing ratio in the Arctic (above 60° N - left) and Antarctic (below 60° S - right) in individual CMIP6 models, for Jun–Aug (blue) and Dec–Feb (yellow). Each line corresponds to one model, and the shaded area marks the ensemble envelope. Only grid points with less than 50% sea ice concentration are considered in this figure. Right: same as left but for cloud fraction. NB: the vertical axis is in logarithmic scale.

A5 *piClim-2xss* scenario

Figure A5. Same as Figure 10 but for total aerosol optical depth (*od*550*aer*).

Figure A6. Difference in air surface temperature in the *piClim-control* and the *piClim-*2xss (left) and *piClim-*2xdust (right) experiments. Models included: IPSL-CM6, NorESM and UKESM. Summer is Jun–Aug in the Arctic, Dec–Feb in the Antarctic, and vice-versa. Values along the x-axis indicate the normalized frequency of temperature changes.

A6 Drivers of sea salt emission trends

969

Figure A7. Historical trends in sea ice concentration (top) and surface wind speed (bottom) in CMIP6 models for the period 1951–2014. Included models are: GISS, HadGEM, MIROC-ES2L, MRI-ESM, NorESM and UKESM. Trends are computed following Mann-Kendall's test. Only significant trends at the 95% level are shown.

-41-

Future trend in sea salt aerosol and sea-ice concentration

Figure A8. Maps of future trends in annual mean sea salt aerosol surface mass mixing ratio (top) and sea-ice concentration (bottom). Scenario SSP585. Multi-model mean from GISS, HadGEM, MIROC-ES2L, MRI-ESM, NorESM and UKESM.

979 Acknowledgments

This project has received funding from the European Union's Horizon 2020 research and innovation programme under grant agreement No 101003826 via project CRiceS (Climate Relevant interactions and feedbacks: the key role of sea ice and Snow in the polar and global climate system). The authors also acknowledge the EU H2020 FORCeS project, contract No 821205. We also appreciate the effort of the CMIP6 modelling groups which contributed the data to the CMIP6 data archive. We acknowledge Yves Balkanski, Jean-Christophe Raut and Dirk Olivié for the fruitful discussions.
