

**Abstract**

We perform a geomagnetic event simulation using a newly developed magnetohydrodynamic with adaptively embedded particle-in-cell (MHD-AEPIC) model. We have developed effective criteria to identify reconnection sites in the magnetotail and cover them with the PIC model. The MHD-AEPIC simulation results are compared with Hall MHD and ideal MHD simulations to study the impacts of kinetic reconnection at multiple physical scales. At the global scale, the three models produce very similar SYM-H and SuperMag Electrojet (SME) indexes, which indicates that the global magnetic field configurations from the three models are very close to each other. We also compare the ionospheric solver results and all three models generate similar polar cap potentials and field aligned currents. At the mesoscale we compare the simulations with in situ Geotail observations in the tail. All three models produce reasonable agreement with the Geotail observations. The MHD-AEPIC and Hall MHD models produce tailward and earthward propagating fluxropes, while the ideal MHD simulation does not generate flux ropes in the near-earth current sheet. At the kinetic scales, the MHD-AEPIC simulation can produce a crescent shape distribution of the electron velocity space at the electron diffusion region which agrees very well with MMS observations near a tail reconnection site. These electron scale kinetic features are not available in either the Hall MHD or ideal MHD models. Overall, the MHD-AEPIC model compares well with observations at all scales, it works robustly, and the computational cost is acceptable due to the adaptive adjustment of the PIC domain.

**1 Introduction**

A geomagnetic storm is a major disturbance of Earth's magnetosphere that occurs when a significant amount of energy is deposited into the geospace. The most widely used and successful simulation tools to study the geomagnetic storms are based on the magnetohydrodynamic (MHD) description, which is computationally feasible to solve. The first global MHD models were developed in the 1980s (LeBoeuf et al., 1981; Wu et al., 1981; Brecht et al., 1981, 1982). Later on, models with more advanced numerical algorithms have been developed, such as the Lyon-Fedder-Mobarry (LFM) (J. G. Lyon et al., 1986; J. Lyon et al., 2004), the OpenGGCM (Raeder et al., 1995, 1996) and the GUMICS (Grand Unified Magnetosphere Ionosphere Coupling Simulation) model (Janhunen, 1996).

In this paper, we use the University of Michigan's Space Weather Modeling Framework (SWMF (Tóth et al., 2012)) which also includes an MHD model, the Block Adaptive-Tree Solar-wind Roe-type Upwind Scheme (BATS-R-US) (Powell et al., 1999) as its global magnetosphere (GM) component. The SWMF has been applied to many storm event simulations (Tóth et al., 2007; Glocer et al., 2009; Haiducek et al., 2017), which is also been selected as the physics-based model at the Space Weather Prediction Center based on a thorough model comparison (Pulkkinen et al., 2013).

Magnetic reconnection plays a key role in the magnetosphere both at the dayside and in the tail. Despite all the successful applications MHD models have achieved, magnetic reconnection in the global MHD models relies on either Hall resistivity, or ad hoc anomalous resistivity, or simply numerical diffusion. The numerical diffusion plays an important role in both ideal and Hall MHD models because it is required to break the field lines. As we show in Appendix A, the reconnection rate remains finite when the grid resolution becomes finer. The Hall resistivity, although does not break the field lines that are frozen into the electron fluid, changes the structure of the reconnection region, which can lead to faster reconnection rate than ideal MHD (Birn et al., 2001). A current dependent anomalous resistivity has also been applied in MHD simulations (Raeder et al., 2001). However, none of these approximations truly describe the physical processes responsible for collisionless reconnection. It is very important to properly represent kinetic

66 reconnection physics in a global simulation and check if it plays an important role in con-  
 67 tributing to the larger scale processes that eventually produce geomagnetic disturbances  
 68 and space weather effects. Furthermore, the MHD approximation assumes that the dis-  
 69 tribution functions of the ions and electrons are Maxwellian. Numerous observations sug-  
 70 gest that this condition is violated especially near the magnetic reconnection sites (L.-  
 71 J. Chen et al., 2016; Burch et al., 2016; Hwang et al., 2019; Lotekar et al., 2020).

72 The MHD with embedded Particle-In-Cell (MHD-EPIC) model (Daldorff et al.,  
 73 2014) enables kinetic physics to be introduced into a global MHD model. The MHD-EPIC  
 74 model has been successfully used to study the interaction between the Jovian wind and  
 75 Ganymede’s magnetosphere (Tóth et al., 2016; Zhou et al., 2019, 2020); flux transfer events  
 76 (FTEs) at the Earth’s dayside magnetopause (Y. Chen et al., 2017); Mars’ magnetotail  
 77 dynamics (Y. Ma et al., 2018) and the dawn-dusk asymmetries discovered at the Mer-  
 78 cury’s magnetotail (Y. Chen et al., 2019). However, the iPIC3D (Markidis et al., 2010)  
 79 code, which is the PIC model used in the MHD-EPIC simulations, can only run on a fixed  
 80 Cartesian grid. The magnetotail (and the associated current sheet that contains the re-  
 81 connection sites) typically exhibits a flapping motion (Tsutomu & Teruki, 1976; Volw-  
 82 erk et al., 2013) during a geomagnetic storms. Covering the whole domain of interest  
 83 where reconnection can occur in the magnetotail would require a very large PIC grid and  
 84 would result in a massive computational cost. This may be feasible for a short simula-  
 85 tion time (up to an hour or so) but geomagnetic storms that usually happen last for days,  
 86 the computational cost would become prohibitive.

87 To tackle this problem, we have developed the MHD with Adaptively Embedded  
 88 PIC (MHD-AEPIC) algorithm that allows smaller PIC region than MHD-EPIC, which  
 89 saves computational resources. Shou et al. (2021) introduces this idea and verifies that  
 90 covering part of the simulation domain with a dynamically moving PIC box gives the  
 91 same solution as using a larger fixed PIC domain, while running significantly faster. This  
 92 justifies our effort to use an adaptive PIC region in the simulation. In this paper, we fur-  
 93 ther improve this method and make it more flexible: 1. The size and shape of the ac-  
 94 tive PIC regions can be adapted during the runtime; 2. The adaptation of the active PIC  
 95 region is fully automatic. To realize the first feature, instead of iPIC3D, we use the FLEKS  
 96 Flexible Exascale Kinetic Simulator (FLEKS) (Y. Chen et al., 2021) as the PIC model. FLEKS  
 97 inherits all numerical algorithms from MHD-EPIC, and also accommodates an adaptive  
 98 PIC grid that allows PIC cells to be turned on and off during the simulation. In addi-  
 99 tion, FLEKS employs a particle splitting and merging scheme to improve the simulation  
 100 efficiency and accuracy. FLEKS is described in more detail in Section 2.2.

101 We have developed a reliable and efficient algorithm to identify potential recon-  
 102 nection sites in the magnetotail using three local criteria. The criteria are easy to com-  
 103 pute and provide the information to the FLEKS code to adapt its grid to cover the re-  
 104 connection sites. This newly developed MHD-AEPIC model is applied to simulate a mag-  
 105 netic storm. The SWMF simulation involves BATSRUS, FLEKS, the ionosphere elec-  
 106 trodynamics model RIM (Ridley et al., 2004) and the inner magnetosphere model RCM  
 107 (Wolf et al., 1982; Toffoletto et al., 2003). This is the first simulation of a real event with  
 108 kinetic reconnection physics in the magnetotail scaling from the global scales of the mag-  
 109 netosphere to the electron scales near the reconnection sites.

110 In this paper, we employ the new model to simulate the magnetic storm of 2011-  
 111 08-05. We cover the tail reconnection sites with the adaptive PIC model. We also per-  
 112 form ideal MHD and Hall MHD simulations for comparison. All simulations are fully  
 113 coupled with the inner magnetosphere and ionospheric electrodynamics models within  
 114 the Space Weather Modeling Framework. We focus on the impact of using ideal MHD,  
 115 Hall MHD and MHD-AEPIC physics on the dynamical processes in the magnetotail. To  
 116 make the comparison straightforward, we use the ideal MHD model at the dayside in all  
 117 three simulations.

118 The computational methods are described in Section 2, the demonstration of the  
 119 adaptation feature and comparisons between models and observations are shown in Sec-  
 120 tion 3 and we summarize in Section 4.

## 121 2 Methods

### 122 2.1 Global Magnetosphere Model: BATS-R-US

123 The Block-Adaptive Tree Solar-wind Roe-type Upwind Scheme (BATS-R-US) is  
 124 used as the Global Magnetosphere (GM) model in our simulation. In the Hall MHD and  
 125 MHD-AEPIC simulations in this paper, the Hall MHD equations (Tóth et al., 2008) are  
 126 solved. The Hall term is handled with a semi-implicit scheme. The spatial discretiza-  
 127 tion uses a 2nd order accurate TVD scheme with the Artificial Wind Riemann solver (Sokolov  
 128 et al., 1999) and the Koren limiter (Koren, 1993) with  $\beta = 1.2$ . The hyperbolic clean-  
 129 ing (Dedner et al., 2003) and eight-wave scheme (Powell et al., 1999) are used to keep  
 130 the magnetic field approximately divergence-free.

131 The Hall MHD equations with a separate electron pressure equation are

$$\frac{\partial \rho}{\partial t} = -\nabla \cdot (\rho \mathbf{u}) \quad (1)$$

$$\frac{\partial(\rho \mathbf{u})}{\partial t} = -\nabla \cdot \left[ \rho \mathbf{u} \mathbf{u} + (p + p_e) \bar{I} + \frac{B^2}{2\mu_0} \bar{I} - \frac{\mathbf{B}\mathbf{B}}{\mu_0} \right] \quad (2)$$

$$\frac{\partial e}{\partial t} = -\nabla \cdot \left[ (\epsilon + p) \mathbf{u} + p_e \mathbf{u}_e + \mathbf{u}_e \cdot \left( \frac{\mathbf{B}^2}{\mu_0} \bar{I} - \frac{\mathbf{B}\mathbf{B}}{\mu_0} \right) \right] + p_e \nabla \cdot \mathbf{u}_e \quad (3)$$

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times \left[ -\mathbf{u}_e \times \mathbf{B} - \frac{\nabla p_e}{ne} \right] \quad (4)$$

$$\frac{\partial p_e}{\partial t} = -\nabla \cdot (p_e \mathbf{u}_e) - (\gamma - 1) p_e \nabla \cdot \mathbf{u}_e \quad (5)$$

132 where  $\bar{I}$  is the identity matrix,  $\rho$  is the mass density,  $\mathbf{u}$  is the plasma bulk velocity,  $\mathbf{B}$   
 133 is the magnetic field,  $p_e$  is the electron pressure,  $p$  is the ion pressure and  $\mathbf{j} = \nabla \times \mathbf{B} / \mu_0$   
 134 is the current density. The Hall velocity and electron bulk velocity are defined as

$$\mathbf{v}_H = -\frac{\mathbf{j}}{ne} = -\frac{M_i}{e} \frac{\mathbf{j}}{\rho} \quad (6)$$

$$\mathbf{u}_e = \mathbf{u} + \mathbf{v}_H \quad (7)$$

135 where  $n = \rho / M_i$  is the number density,  $M_i$  is the ion mass, and  $e$  is the elementary charge.  
 136 The total energy density is defined as

$$e = \epsilon + \frac{B^2}{2\mu_0} = \frac{1}{2} \rho \mathbf{u}^2 + \frac{p}{\gamma - 1} + \frac{\mathbf{B}^2}{2\mu_0} \quad (8)$$

137 where  $\epsilon = \rho \mathbf{u}^2 / 2 + p / (\gamma - 1)$  is the hydrodynamic energy density of the ions and  $\gamma =$   
 138  $5/3$  is the adiabatic index. The thermal energy density of the electrons is  $\epsilon_e = p_e / (\gamma -$   
 139  $1)$ . We note that the  $e + \epsilon_e$  is conserved both analytically and numerically as the non-  
 140 conservative source terms  $\pm p_e \nabla \cdot \mathbf{u}$  in equations (3) and (5) cancel out. Apart from  $(\rho, \mathbf{u}, \mathbf{B}, p, p_e)$ ,  
 141 other variables are derived quantities.

142 The continuity equation (1), momentum equation (2), energy equation (3) and elec-  
 143 tron pressure equation (5) are solved with an explicit time stepping scheme. In the in-  
 144 duction equation (4), the convection term  $\mathbf{u} \times \mathbf{B}$  and pressure gradient term  $\nabla p_e / ne$   
 145 are solved using an explicit scheme, while the Hall term  $\mathbf{v}_H \times \mathbf{B}$  is advanced with an  
 146 implicit scheme. The Hall MHD equations introduce whistler mode wave, which has a  
 147 characteristic wave speed inversely proportional to the wavelength. The shortest wave-  
 148 length that exists in a numerical simulation is proportional to the cell size  $\Delta x$ , so the  
 149 fastest whistler wave speed in a simulation is proportional to  $1/\Delta x$ . The time step in

150 a fully explicit scheme is limited by the Courant-Friedrichs-Lewy (CFL) condition:  $\Delta t <$   
 151  $\Delta x/c_{\max}$ , where  $c_{\max}$  is the fastest wave speed, which leads to a time step proportional  
 152 to  $1/(\Delta x)^2$ . We use a semi-implicit scheme (Tóth et al., 2012) to handle the stiff Hall  
 153 term in the induction equation, so that the time step of the explicit part is only limited  
 154 by the fast magnetosonic wave speed instead of the whistler speed.

155 A three-dimensional block-adaptive Cartesian grid is used to cover the entire compu-  
 156 tational domain  $-224R_E < x < 32R_E$ ,  $-128R_E < y, z < 128R_E$  in GSM coord-  
 157 inates. The Hall effect is restricted to  $x \in [-100R_E, 20R_E]$ ,  $|y| < 30R_E$  and  $|z| <$   
 158  $20R_E$  box region excluding a sphere of radius  $3R_E$  centered at the Earth to speed up  
 159 the simulation. Outside this region the Hall effect is neglected by setting  $\mathbf{v}_H = 0$ . In  
 160 the magnetosphere, the smallest ion inertial length  $d_i = c/\omega_{pi}$  is about  $1/20 R_E$  in the  
 161 tail lobe region, which is already extremely difficult for a 3-D global MHD model to re-  
 162 solve, let alone the PIC code. Tóth et al. (2017) introduced a scaling approach which  
 163 scales up the kinetic length by artificially increasing ion mass per charge by a scaling fac-  
 164 tor. The scaling does not change the fluid variables, such as density, pressure, velocity,  
 165 IMF and dipole field, and the global structure of the magnetosphere will not change sig-  
 166 nificantly as long as the scaled up ion inertial length is much smaller than the global scales.  
 167 In this paper, we use a factor of 16, which satisfies this condition. On the other hand,  
 168 with the ion inertial length scaled up by 16 times, we don't need an extremely fine grid  
 169 to resolve it. We set the grid cell size in the magnetotail to  $\Delta x = 1/4R_E$ , which is about  
 170 4 times smaller than the scaled up ion inertial length. About fourteen million cells are  
 171 used in total.

172 At the inner boundary  $r = 2.5R_E$ , the density is calculated by the empirical for-  
 173 mula  $\rho_{\text{inner}} = (28 + 0.1\text{CPCP}) \text{ amu/cm}^3$ , where CPCP is the average of the northern  
 174 and southern cross polar cap potentials measured in keV. This boundary condition has  
 175 been used successfully in previous geomagnetic storm simulations (Pulkkinen et al., 2013).  
 176 The pressure and magnetic field  $\mathbf{B}_1$  have zero gradient at the inner boundary, while the  
 177 radial velocity is set to zero and the tangential velocity is calculated from the corota-  
 178 tion and the  $\mathbf{E} \times \mathbf{B}$  drift, where the electric field  $\mathbf{E}$  is provided by the Ridley Ionosphere  
 179 Model (RIM) (Ridley et al., 2004).

## 180 2.2 Particle-in-cell Model: FLEKS

181 The FLEKS (Flexible Exascale Kinetic Simulator) (Y. Chen et al., 2021) is used  
 182 as the particle-in-cell (PIC) model (PIC component in the SWMF) to resolve kinetic physics.  
 183 FLEKS uses the same two-way coupling method as MHD-EPIC (Daldorff et al., 2014)  
 184 and the Gauss's law satisfying energy-conserving semi-implicit method (GL-ECSIM) (Y. Chen  
 185 & Tóth, 2019) for the PIC solver. To enable the adaptation in MHD-AEPIC, FLEKS  
 186 introduces an adaptive grid that allows changing simulation region dynamically. Figure  
 187 1 shows a schematic plot of the adaptive grid. We choose  $\Delta x = 1/4R_E$  to be the PIC  
 188 grid resolution so that the scaled  $d_i/\Delta x \sim 4$ . The ion inertial length inside the mag-  
 189 netosphere is described in Subsection 2.1. The ion-electron mass ratio is set to 100 in  
 190 this simulation so that the electron skin depth  $d_e = 0.1d_i$ . Li et al. (2019) perform 2-  
 191 D PIC simulations using different ion-electron mass ratios and conclude that features  
 192 like reconnection rate and magnetic energy conversion are similar in simulations using  
 193 different ion-electron mass ratios. Although the grid is not refined to resolve the elec-  
 194 tron scale, in the PIC model the electron particles can resolve sub-grid scale physics un-  
 195 der the influence of the electromagnetic field that is resolved on the ion scale. Y. Chen  
 196 and Tóth (2019) show that the semi-implicit PIC model can reproduce the most impor-  
 197 tant ion scale features of magnetic reconnection with such grid resolution. The selected  
 198 resolution balances between the computational cost and the requirement of resolving ki-  
 199 netic scales.

FLEKS provides a particle merging and splitting scheme to maintain the number of particles per cell within bounds. Merging particles in a cell with high number of particles can improve load-balancing and speed up simulation, while splitting particles in a cell with few particles can reduce noise and improve accuracy for the PIC simulation. This feature is very useful keeping the number of particles per cell about uniform during a long geomagnetic storm simulation.

### 2.3 Selection Criteria of PIC Regions

As described in the previous section, FLEKS allows patches to be turned on and off during the simulation. To make the active PIC patches only cover the regions of interest, where magnetic reconnection is happening or will be triggered soon, the MHD model should locate these regions and pass this information to FLEKS. Finding the locations of magnetic reconnection sites can be done in various ways including tracing field lines (Glocer et al., 2016). For sake of efficiency and generality, here we use local criteria based on the local MHD solution only.

Magnetic reconnection usually happens in current sheets where the current density  $j$  is strong and the magnetic field  $B$  is weak. In particular, the field  $B_{\perp}$  that is perpendicular to the current  $\mathbf{j}$  should be close to zero, while the guide field parallel to the current can be non-zero. We define the following non-dimensional relation as our first criterion

$$\frac{J\Delta x}{B_{\perp} + \varepsilon} = \frac{J^2\Delta x}{|\mathbf{J} \times \mathbf{B}| + J\varepsilon} > c_1 \quad (9)$$

where  $\mathbf{J} = \mu_0\mathbf{j} = \nabla \times \mathbf{B}$  and  $\varepsilon$  is a small dimensional constant in units of the magnetic field introduced to avoid dividing by zero. We use  $\varepsilon = 1$  nT in our simulations presented here, which is much smaller than the typical magnetic field intensity in the tail current sheet.  $\Delta x$  is the local cell size that is used in calculating the curl of the magnetic field, so that  $J\Delta x$  is the jump of the transverse magnetic field between neighboring grid cells. We set  $c_1 = 0.8$  in this work to select the cells that are close to the reconnection sites.

While criterion (9) works quite well in general, we sometimes find that it selects the axis of flux ropes, or O-lines, in addition to X-lines, especially if  $\varepsilon$  is very small. Reconnection does not occur at O-lines, so we developed a second criterion that distinguishes X- and O-lines based on the divergence of the magnetic field curvature vector:

$$[\nabla \cdot (\mathbf{b} \cdot \nabla \mathbf{b})](\Delta x)^2 > c_2 \quad (10)$$

where  $\mathbf{b} = \mathbf{B}/|\mathbf{B}|$  is a unit vector along the magnetic field. We use  $c_2 = -0.1$  to identify X-lines where the curvature vectors point away from the X-line, so their divergence is positive.

The above two criteria are identifying potential magnetic reconnection sites through local plasma properties in a general scenario. However, current sheets in the solar wind can also satisfy those two criteria. To make the selection more selective, we need to introduce a third criterion to exclude the volume outside the magnetosphere. Observations show that specific entropy is two orders of magnitude larger in the magnetosphere than in the magnetosheath (X. Ma & Otto, 2014) and our simulations properly reproduce these properties. Here we use the specific entropy as the third criterion:

$$\frac{p}{\rho^\gamma} > c_3 \quad (11)$$

where  $p$  is the plasma thermal pressure,  $\rho$  is the plasma density, and  $\gamma = 5/3$  is the ratio of the specific heats (Birn et al., 2006, 2009). Different from the  $c_1$  and  $c_2$  introduced above, this criterion is dimensional and we use the threshold value  $c_3 = 0.02$  nPa/cm<sup>-3 $\gamma$</sup> .

243 The three criteria combined can identify X-lines in the magnetotail well. To make  
 244 the active PIC region large enough around the X-lines, we flag all patches where all three  
 245 criteria are met, and then activate all patches within a distance  $L_x$ ,  $L_y$  and  $L_z$  from these  
 246 flagged patches in the  $x$ ,  $y$  and  $z$  directions, respectively. The extension in each direc-  
 247 tion enables the PIC model to cover a buffer area outside the reconnection sites. This  
 248 buffer ensures that the velocity distribution of ions and electrons at the boundary of the  
 249 PIC region can be well approximated with a drifting Maxwellian distribution, which re-  
 250 sults in a consistent coupling between the MHD model. We use  $L_x = 4R_E$  and  $L_y =$   
 251  $L_z = 2R_E$  in this work.

252 Each MPI process of BATS-R-US calculates the above criteria on their respective  
 253 sub-domains overlapping with the PIC grid and activate the patches of the PIC grid where  
 254 all 3 criteria are satisfied. Then the processors collect the information: a PIC patch is  
 255 activated if any of the BATS-R-US processes activated it. Since the status of all PIC patches  
 256 (on/off) is stored in each MPI processor of BATS-R-US, using the default logical array  
 257 would consume a lot of memory. To reduce the memory use, the status is stored by a  
 258 single bit, which is 32 times smaller than the size of the default logical variable in For-  
 259 tran. The information is conveniently collected with the bitwise "or" operator `MPI_BOR`  
 260 used in the `MPI_ALLREDUCE` call.

## 261 2.4 Ionospheric Electrodynamics Model: RIM

262 The Ionospheric Electrodynamics (IE) is simulated by the Ridley Ionosphere Model  
 263 (RIM) (Ridley et al., 2004) that solves a Poisson-type equation for the electric poten-  
 264 tial on a 2-D spherical grid. In this work, the grid resolution is set to  $2^\circ$  in both longi-  
 265 tude and latitude directions. The lower latitude boundary is at  $10^\circ$  where the electric  
 266 potential is set to zero.

267 The BATS-R-US and RIM models are two-way coupled every 5 seconds. To cal-  
 268 culate the Poisson-type equation, RIM obtains the field-aligned currents (FAC) calcu-  
 269 lated at  $3R_E$  from the BATS-R-US model and maps them down to its grid. The F10.7  
 270 flux is also an input parameter of RIM that is used together with the FAC to calculate  
 271 the particle precipitation and conductances based on an empirical model. The electric  
 272 field calculated by the RIM is mapped back to the inner boundary of BATS-R-US to ob-  
 273 tain the  $\mathbf{E} \times \mathbf{B}/B^2$  velocity for its inner boundary condition. The cross polar cap po-  
 274 tentials (CPCP, (the difference of the maximum and minimum potentials in the two hemi-  
 275 spheres) are also sent to BATS-R-US to set the density at the inner boundary.

## 276 2.5 Inner Magnetosphere Model: RCM

277 The Inner Magnetosphere (IM) is modeled by the Rice Convection Model (RCM)  
 278 (Wolf et al., 1982; Toffoletto et al., 2003). The standard RCM settings are used, includ-  
 279 ing an exponential decay term with a 10-hour e-folding rate. The decay term makes the  
 280 Dst index recover better after strong storms. As a component of the SWMF geospace  
 281 model, RCM is used in all simulations presented in this paper.

282 The RCM model is one-way coupled with RIM and two-way coupled with BATS-  
 283 R-US every 10 seconds. RIM sends the electric potential to RCM, where it is used to  
 284 advect the field lines with the  $\mathbf{E} \times \mathbf{B}/B^2$  drift. In the two-way coupling between BATS-  
 285 R-US and RCM, BATS-R-US identifies the closed field line regions and calculates field  
 286 volume integrals of pressure and density (De Zeeuw et al., 2004). The integrated pres-  
 287 sure and density are applied to RCM as the outer boundary condition with the assump-  
 288 tion of 90%  $H^+$  and 10%  $O^+$  number density composition. From RCM to BATS-R-US,  
 289 the GM grid cell centers are traced to the RCM boundary along the magnetic field lines  
 290 (De Zeeuw et al., 2004) and the BATS-R-US pressure and density are pushed towards  
 291 the RCM values with a 20s relaxation time.

### 3 3D Global Simulation with Kinetic Physics in the Magnetotail

#### 3.1 Simulation Setup

We apply the MHD-AEPIC method to the geomagnetic storm event of Aug. 6, 2011 with an observed minimum Dst  $-126$  nT. Previous modeling works show frequent flapping motion of the magnetotail current sheet during the storm (Tsutomu & Teruki, 1976; Volwerk et al., 2013), so the adaptive embedding feature is perfect for only covering the current sheet during the simulation. We start our simulation at 2011-08-05 15:00:00 and end it at 2011-08-06 07:00:00. This time range covers the main phase and the early recovering phase of the storm when the largest geomagnetic impact happens. The solar wind inputs are shown in Figure 2. First the BATS-R-US and RIM models are run to reach a quasi-steady state after 50k iteration steps using local time stepping. Figure 3 shows the plasma density along with the different refinement level boundaries of the AMR grid in the meridional plane for the steady state solution. Then the SWMF is switched to a time-accurate mode with FLEKS and RCM models turned on. Y. Chen et al. (2017) and Zhou et al. (2020) study the dayside reconnection at Earth and Ganymede by putting PIC regions at the magnetopause. They also compare the results with Hall MHD and conclude that the two models generate similar global features, such as flux rope formation and reconnection rate. In this paper, we only put PIC regions in the magnetotail, for sake of controlling variants. The dayside reconnection is modeled by the ideal MHD. The computational domain of FLEKS is determined by the selection criteria introduced above. For sake of comparison, we also conduct two other simulations without FLEKS: one with Hall MHD model and the other with ideal MHD model.

#### 3.2 PIC Region Adaptation

In this subsection, we highlight the utility and efficiency of the adaptive embedding scheme. Figure 4 illustrates how the PIC region is changing over the simulation. Panels (a)-(f) are snapshots from six different times. The color contours show the  $j_y$  component of the current density on the meridional plane to show the magnetospheric current system. Boundaries of the active PIC region are shown by the gray isosurface. Snapshots 4 (a) and (b) are taken before the sudden commencement of the storm. At this time, the IMF  $B_z$  is pointing northward and the solar wind speed is about 400 km/s. From the isosurface plot, the PIC region is covering the tail current sheet tilting southward. In Figure 4 (b), the tail current sheet is kinked and the PIC region adjusts its shape to accommodate the tail current sheet. Snapshots 4 (c)-(f) are taken after the sudden commencement of the storm. Here we observe a much compressed magnetosphere as well as an enhanced current density. In the last two snapshots, the tail current sheet is tilting northward and it is well covered by the PIC region. From the snapshots, we can conclude that the PIC region selection criteria work well in identifying the tail current sheet, which can make the PIC region accommodate with the flapping motion of the magnetotail. The translucent red line in Figure 4 (g) shows the volume of the active PIC region recorded every second from the simulation, while the solid red line is the volume smoothed over every minute. The Dst index is also presented in the background for reference. The volume of the PIC region increases after the sudden commencement and starts dropping in the recovering phase. This reflects that the tail current system intensity is related to the solar wind condition. Notice that the volume is less than  $2000 R_E^3$  for the entire storm simulation, which is only about 1.4% of the large PIC box extending from  $-100R_E$  to  $-10R_E$  in the  $x$  direction and  $-20R_E$  to  $20R_E$  in the  $y$  and  $z$  directions. This confirms that the MHD-AEPIC method saves substantial amount of computational resources.

### 3.3 Global Scale: Geomagnetic Indexes and Ionospheric Quantities

341

342

343

344

345

346

347

348

349

350

351

To evaluate the models' performance at the global scale, we use the SYM-H and SME as evaluation metrics. The SYM-H index approximates the symmetric portion of the northward component of the magnetic field near the equator based on measurements at six ground magnetometer stations. This index characterizes the strength of the ring current (Ganushkina et al., 2017) and it is an indicator of storm activity. The SYM-H data with a 1-minute cadence is downloaded from NASA OMNIWeb Data Service. The SuperMAG electrojet (SME) index is an indicator of substorms and auroral power (Newell & Gjerloev, 2011). SME utilizes more than 100 ground magnetometer stations at geomagnetic latitudes between  $+40^\circ$  and  $+80^\circ$ , which resolves the large and extreme events more effectively than the traditional Auroral Electrojets (AE) index (Davis & Sugiura, 1966; Bergin et al., 2020).

352

353

354

355

356

357

358

359

360

361

362

In our model, the simulated SYM-H is calculated by evaluating the Biot-Savart integral at the center of the Earth from all currents in the simulation domain. Calculating SME is more complicated: the magnetic field disturbances are calculated at the positions of the 100+ ground magnetometer stations and the simulated SME is obtained following the SuperMAG procedure. From Figure 5, the MHD-AEPIC produces geomagnetic indexes close to the other two MHD models. The SYM-H plot shows that the initial, main and recovery phases of the storm event are reproduced by all three models reasonably well. However, the models cannot reproduce the lowest SYM-H values that correspond to the strongest observed geomagnetic perturbations. This feature can also be observed in the SME plots: all three models produce increased auroral electrojets, however the second and third enhancements are weaker than the observed values.

368

369

370

371

372

373

374

Apart from the global indexes such as SYM-H and SME, it is also important to compare the amount of energy that the solar wind and interplanetary magnetic field (IMF) transfer to Earth's magnetosphere-ionosphere system through direct driving. The cross polar cap potential (CPCP) is an indicator of this energy transfer process (Troshichev et al., 1988, 1996). The CPCP is not directly measured but can be derived from observations using the Assimilative Mapping of Ionospheric Electrodynamics (AMIE) (Richmond & Kamide, 1988) technique or from the Defense Meteorological Satellite Program (DMSP) measurements (Hairston et al., 1998). Another approach based on the Super Dual Auroral Radar Network (SuperDARN) observations (Ruohoniemi & Greenwald, 1998) usually underestimates the CPCP significantly. We opt to use the readily available Polar Cap Index (PCI) from the OMNIWeb website and convert it into CPCP using the empirical relationship derived by Ridley and Kihn (2004):

$$\text{CPCP}_{\text{North}} = 29.28 - 3.31 \sin(T + 1.49) + 17.81\text{PCI}_N \quad (12)$$

375

376

377

378

379

380

where  $T$  is the month of the year normalized to  $2\pi$ . The storm event in this paper is in August, so  $T = (8 - 1) * 2\pi/12$ . Gao (2012) showed that this formula provides good agreement with AMIE and DMSP based approaches. For the southern hemisphere, since there is no published empirical relationship between southern CPCP and PCI, we change the sign in front of the  $\sin(T+1.49)$  term (expressing the seasonal dependence) in the formula:

$$\text{CPCP}_{\text{South}} = 29.28 + 3.31 \sin(T + 1.49) + 17.81\text{PCI}_S \quad (13)$$

381

382

The simulated CPCP is defined as the difference between the maximum and the minimum of the electric potential obtained from the RIM model for both hemispheres.

383

384

385

386

387

388

Figure 6 (a) shows the northern and southern cross polar cap potentials from the three models together with the CPCP derived from the PCI. In general, the results from the three models are very close to each other and have good agreements with the PCI derived CPCP for both hemispheres. Notice that the PCI is derived from a single station for each hemisphere while the model calculates CPCP using the entire electric potential. The differences between the model output and CPCP could be because the PCI is

not measuring the ionospheric dynamics for the entire polar region. We observe that the three models generate the most different CPCP results during the main phase of the storm event at around  $t = 2011-08-05\ 22:00:00$ . Figure 6 (b) shows the polar cap potential and radial component of the field aligned currents for both hemispheres. The structure of the electric potentials as well as the field aligned currents are very similar among the three models.

The geomagnetic indexes and ionospheric quantities demonstrate that introducing kinetic physics in the magnetotail does not change the global configuration of the simulated magnetosphere and ionosphere significantly relative to the ideal and Hall MHD simulations. It is to be seen if this trend persists for other storms, especially extreme events.

### 3.4 Mesoscale: Magnetotail Dynamics

During the storm event, the Geotail spacecraft was in the magnetotail at  $x \approx -29 R_E$  crossing the equatorial plane and approaching to the meridional plane. Figure 7 shows the magnetic field and ion moments observed by Geotail and compares them with the ideal-MHD, Hall-MHD and MHD-AEPIC simulations. The MHD-AEPIC model shows a reasonable agreement with the Geotail number density observation before  $t = 2011-08-06\ 00:00$ , including the current sheet crossing event between  $t = 2011-08-05\ 22:00$  and  $t = 2011-08-05\ 23:00$  while the Hall-MHD model overestimates the ion number density substantially. However, all three models generate much higher number density than observed after  $t = 2011-08-06\ 00:00$ . None of the three models show perfect agreement with the magnetic field observations. The  $B_x$  component gives us information about which side of the current sheet the satellite is. The comparison plot shows that the virtual satellites in the simulations are all on the opposite side of the current sheet than Geotail before  $t = 2011-08-05\ 22:00$ . Between  $t = 2011-08-05\ 23:00$  and  $t = 2011-08-06\ 01:00$ , Geotail is crossing the current sheet from the north side to the south side, and this is captured by all three models. However, the next current sheet crossing at around  $t = 2011-08-06\ 01:30$  is not captured by MHD-AEPIC and ideal-MHD. The Hall-MHD simulations produces a similar structure but with a 30-minute time shift. The  $B_y$  and  $B_z$  components give information about flux rope structures. All three models provide good agreement with the observation in terms of overall field magnitude, while it is difficult to tell which one is better in capturing fine details. Geotail observed a  $B_z$  reversal along with a relatively strong core  $B_y$  at around  $t = 2011-08-06\ 05:00$ , which indicates a flux rope. A similar structure is produced by MHD-AEPIC with a 30-minute delay, while there is no similar signal from the ideal-MHD and Hall-MHD simulations. Geotail observed high ion speed around 1000 km/s at  $t = 2011-08-06\ 02:00$  and  $t = 2011-08-06\ 03:00$ . The MHD-AEPIC model only generates around 500 km/s ion speeds. Although the ideal-MHD and Hall-MHD models can produce maximum ion speeds around 1000 km/s, they also generate large scale oscillations that are not present in the observations. Overall, introducing kinetic physics in the magnetotail did not improve plasma and magnetic features compared to the ideal MHD simulation at the mesoscale. The Hall MHD simulation, on the other hand, produces significantly more oscillations than observed in multiple time periods.

Since Geotail only observes along a single trajectory, it cannot provide insight into the full dynamics of the magnetotail. To compare the different models, we plot results on 2-D surfaces. Figure 8 shows the magnetosphere simulation results from three models at the same time 2011-08-05 19:40:00. Figure 8 (a1), (b1) and (c1) show the  $x$  component of the ion bulk velocity and magnetic field lines in the meridional plane ( $-80 R_E < x < -5 R_E$  and  $-20 R_E < z < 10 R_E$ ) from MHD-AEPIC, Hall MHD and ideal MHD simulations, respectively. The global configurations of the magnetosphere share a lot of similarities but there are several differences as well. All three models give a southward tilted magnetotail that is compressed most in the  $z$  direction at around  $x = -40 R_E$  as a result of the IMF structure. In terms of the reconnection feature, all three models

441 generate X-lines in the tail current sheet at around  $x = -20 R_E$  and  $z = -5 R_E$ . Di-  
 442 verging reconnection ion jets are generated at the major X-line for all three models.

443 To analyze physical quantities in the current sheet better, we extract the quanti-  
 444 ties along a surface where  $B_x = 0$  and project this surface to the  $x-y$  plane for plot-  
 445 ting. The bottom row in Figure 8 shows the  $z$  coordinate of the center of the current sheet.  
 446 The structure is similar as in the meridional plane plots: the current sheets are at  $z \approx$   
 447  $0$  near Earth and at  $z \approx -15 R_E$  at far tail for MHD-AEPIC and Hall MHD models,  
 448 while  $z \approx -12 R_E$  for ideal MHD. Figure 8 (a2)-(c2) show the ion bulk flow speed on  
 449 the current sheet surface. There are significant differences among the three models in  
 450 the earthward ion flow structures. For ideal MHD, the earthward ion flow is distributed  
 451 roughly symmetrically at  $-3 R_E < y < 3 R_E$ . The earthward ion jet generated by Hall  
 452 MHD can only be observed on the dawn side at  $-5 R_E < y < 0$ . The MHD-AEPIC  
 453 simulation produces earthward ion jet both on the dawn and dusk sides. However, the  
 454 ion jet on the dawn side is further away from the earth than the jets on the dusk side.  
 455 Also, the earthward ion jets can be observed from  $-5 R_E$  to  $7 R_E$  in the  $y$  direction, which  
 456 agrees with the observations that earthward flows are observed at a wide range of  $y$  val-  
 457 ues (Angelopoulos et al., 1994).

458 Although the earthward ion flow from MHD-AEPIC is different from pure MHD  
 459 models, the similar magnetic field structure and current sheet position indicate that these  
 460 snapshots from different models represent the same physical state of the magnetosphere.  
 461 Hence, it is valid to examine the flux rope features based on these results. As first pro-  
 462 posed to be formed in the Earth's magnetotail (Schindler, 1974), magnetic flux ropes are  
 463 reported to be closely related to magnetic reconnection by various observations and sim-  
 464 ulations (Hones Jr et al., 1984; Slavin et al., 1989; Daughton et al., 2006; Markidis et  
 465 al., 2013). The observational characteristics of the flux ropes are a pair of positive and  
 466 negative  $B_z$  signatures with a core magnetic field  $B_y$  in between. Hence, we plot the  $B_z$   
 467 and  $|B_y|$  components on the current sheet surface in Figure 8(a-c)(2-3). Panels (c3) and  
 468 (c4) show only one flux rope at  $-40 R_E$  and there is no evidence indicating flux rope ex-  
 469 ists at the near earth plasma sheet from  $-40 R_E$  to the Earth based on the ideal MHD  
 470 model results. The Hall MHD and MHD-AEPIC give very different flux rope occurrence  
 471 (Figure 8 (a-b)(3-4)) from ideal MHD. In addition to the moving directions of the flux  
 472 ropes, the diameter of the flux ropes also varies: the earthward flux ropes are observed  
 473 as smaller ones. This difference has been reported in a thorough analysis of Geotail ob-  
 474 servations (Slavin et al., 2003). By examining the flux ropes as a mesoscale feature, we  
 475 can conclude that by modeling the reconnection physics better, the MHD-AEPIC and  
 476 Hall MHD simulations produce more flux ropes in the magnetotail than ideal MHD as  
 477 well as distinguish two types of the flux ropes. However, there is no evidence support-  
 478 ing that MHD-AEPIC can produce better mesoscale features than Hall MHD. This could  
 479 be the case because the spatial scale of the flux ropes is much larger than the kinetic scale  
 480 which PIC model is resolving.

481 Figure 9 shows different physical quantities near the reconnection X-line at the same  
 482 time as Figure 8. Panel (a) shows the current density of the current sheet  $j_y$ , the out-  
 483 of-plane magnetic field  $B_y$  and the ion bulk velocity  $U_{ix}$  from the ideal MHD model. The  
 484 current sheet is smooth and narrow around the X-line. The simulation produces diverg-  
 485 ing ion outflow as expected. There is no significant  $B_y$  near the reconnection site due  
 486 to the lack of Hall physics in the ideal MHD model. Panel (b) shows the same quanti-  
 487 ties as Panel (a) for the Hall MHD model. In addition, the bottom plot shows the elec-  
 488 tron velocity in the  $x$  direction calculated from the ion bulk velocity and the Hall veloc-  
 489 ity as  $u_{ex} = u_{ix} - j_x/(ne)$ . Different from the current sheet in the ideal MHD model,  
 490 the current sheet in the Hall MHD simulation breaks up at multiple locations. There are  
 491 strong  $B_y$  signatures in the Hall MHD simulation as expected from Hall physics, although  
 492 the presence of the non-uniform guide field somewhat distorts the classical quadrupo-  
 493 lar structure. The diverging ion bulk flow is very similar to the diverging electron flow,

494 because the  $j_x$  component of the current is weak. Panel (c) shows the same quantities  
 495 as Panel (b) from the MHD-AEPIC model with an extra ion nongyrotropy measure  $D_{ng,i}$ .  
 496 The current sheet in the MHD-AEPIC simulation also forms multiple flux ropes simi-  
 497 lar to the Hall MHD results. The MHD-AEPIC model also generates the Hall magnetic  
 498 field  $B_y$ . The ion and electron velocities from the MHD-AEPIC show very clear inflow  
 499 and outflow features that are quite different from the Hall MHD solution. While both  
 500 ideal and Hall MHD assume isotropic pressures, the PIC simulation allows a general pres-  
 501 sure tensor with anisotropy and even nongyrotropy (non-zero off-diagonal terms). Aunai  
 502 et al. (2013) defines the nongyrotropy measure as

$$D_{ng} = 2 \frac{\sqrt{P_{12}^2 + P_{23}^2 + P_{13}^2}}{P_{11} + P_{22} + P_{33}} \quad (14)$$

503 Here  $P_{ij}$  are the pressure tensor components in the local magnetic field aligned coordi-  
 504 nate system. The  $D_{ng}$  quantity produced by the MHD-AEPIC model shows that the ion  
 505 nongyrotropy increases near the X-line. In conclusion, both Hall MHD and MHD-AEPIC  
 506 generate more features than the ideal MHD model. The MHD-AEPIC and the Hall MHD  
 507 models generate similar Hall magnetic field structures and current sheet features. The  
 508 MHD-AEPIC model generates distinct ion and electron bulk flows, as well as the nongy-  
 509 rotropic pressure distribution near the X-line.

### 510 3.5 Kinetic Scale: Electron Velocity Distribution Function

511 In this subsection, we will demonstrate that the kinetic physics at the reconnection  
 512 site is also properly captured by the MHD-AEPIC model. The magnetic reconnection  
 513 is regarded as one of the most fundamental physical processes to transfer energy from  
 514 magnetic field to plasma. Since the launch of the Magnetospheric Multiscale (MMS) mis-  
 515 sion (Burch et al., 2016), magnetic reconnection has been observed at the electron scale  
 516 during multiple satellite crossings of the electron diffusion region (EDR) (Webster et al.,  
 517 2018). The EDR encounters exhibit electron nongyrotropy, which can be recognized by  
 518 a crescent-shaped electron distributions (Torbert et al., 2018).

519 Figure 10 compares the MHD-AEPIC simulation with MMS observations (Hwang  
 520 et al., 2019). Panel (a) is a contour plot of ion bulk velocity in the meridional plane at  
 521  $t = 2011-08-05\ 23:20:00$ . The ion jets, a clear signature of magnetic reconnection, are  
 522 shown by the blue and red colors. The dashed white line near the X-line, which is ro-  
 523 tated about  $13.3^\circ$ , is the  $L$  direction of the local reconnection coordinate system. We also  
 524 found that the  $M$  axis is aligned with the  $y$  axis in GSM. So the LMN coordinate vec-  
 525 tors for this reconnection event are  $L = (0.972, 0, 0.233)$ ,  $M = (0, 1, 0)$  and  $N = (-0.233, 0, 0.972)$ .  
 526 The electron velocities are shown in the LMN coordinate system to allow a direct com-  
 527 parison with the MMS observations. Panels (b) and (d) show the electron velocity dis-  
 528 tribution functions (VDF) from the model and the MMS observation. The simulation  
 529 VDF of the electrons is collected inside an ellipsoid region centered at  $(-30.6, 0.5, -0.9)$   $R_E$   
 530 with principle semi-axes  $(0.3, 2.5, 0.3)$   $R_E$  in the  $(x, y, z)$  directions, respectively. The  
 531 red circle in panel (a) labeled by B is the cross section of the ellipsoid with the merid-  
 532 ional plane. The choice of the ellipsoid shape is based on panel (c) that shows where the  
 533 MMS observations were taken with respect to the reconnection site according to Figure  
 534 2 by Hwang et al. (2019). The MMS3 observations of the electron VDF (Hwang et al.,  
 535 2019) at the location  $(-18.1, 7.30, 0.66)$   $R_E$  are shown in panel (d). Although the sim-  
 536 ulation and observation are not from the same event and the EDR is not at the same  
 537 position in GSM coordinates, the electron data is collected at a similar location relative  
 538 to the X-line and the velocity components are all projected to the LMN coordinates (see  
 539 panels (a) and (c)).

540 This suggests that we can directly compare the two VDF plots in panels (b) and  
 541 (d), and they indeed agree very well. The agreement is not only qualitative, but in fact  
 542 quantitative. Since the ion-electron mass ratio is 100, the simulated electron velocity is

543 multiplied by  $\sqrt{\frac{m_{i,\text{real}}}{m_{e,\text{real}}}/\frac{m_{i,\text{simulation}}}{m_{e,\text{simulation}}}} \approx \sqrt{18.36} \approx 4.28$  to be comparable with the obser-  
 544 vations. In both panels the velocity distribution extends to  $\pm 40,000$  km/s in the  $N$  di-  
 545 rection and  $(-40,000, +20,000)$  km/s in the  $M$  direction. A non-Maxwellian core dis-  
 546 tribution can also be clearly identified in both panels at  $-20,000$  km/s  $< v_y < 10,000$  km/s)  
 547 and  $|v_z| < 10,000$  km/s. In addition to the electron diffusion region, we also collected  
 548 electrons inside two other ellipsoids at the inflow (labeled by A) and outflow (labeled by  
 549 C) regions. The semi-axes of these two ellipsoids are the same as before while the cen-  
 550 ters of the ellipsoids are  $(-28.5, 1.5, 0.5) R_E$  and  $(-33.0, 1.5, -1.0) R_E$  in the  $(x, y, z)$   
 551 directions, respectively. Panels (e) and (f) shows the electron VDF in  $L - N$  and  $L -$   
 552  $M$  coordinates, the distribution can be characterized as a bidirectional beam distribu-  
 553 tion (Asano et al., 2008). The distribution functions at outflow region in panels (g) and  
 554 (h) are almost circles with shifted centers indicating the direction of the bulk velocities.  
 555 The distribution functions from the inflow and outflow also agree very well with the ex-  
 556 isting theories (Pritchett, 2006; Egedal et al., 2010). Hence, we can conclude that an MHD-  
 557 AEPIC global simulation can generate electron phase space distributions that are very  
 558 close to the MMS observations, and reproduces the main features of reconnection physics  
 559 even at the electron scales.

## 560 4 Conclusions and Discussions

561 In this paper, we introduced a newly developed magnetohydrodynamic with adap-  
 562 tively embedded particle-in-cell (MHD-AEPIC) model. The MHD-AEPIC allows PIC  
 563 grid cells to be turned on and off during the simulation based on the physical criteria  
 564 provided. Different from the previous MHD-EPIC model, which requires a fixed Carte-  
 565 sian box to cover the PIC region, the MHD-AEPIC model enables PIC regions moving  
 566 with the reconnection sites to save computational resources substantially. During the  
 567 main phase of the storm, from  $t = 2011-08-06$  00:05:00 to  $t = 2011-08-06$  02:54:00, when  
 568 the volume of the PIC domain is about  $1500 R_E^3$ . The relative timings are the follow-  
 569 ing: 72.72% of CPU time is used on FLEKS, 13.26% is for BATS-R-US and 10.35% is  
 570 taken by the coupling between FLEKS and BATS-R-US. The rest 3.67% of CPU time  
 571 is consumed by RIM, RCM and the overhead of the SWMF. For the entire 16-hour ge-  
 572 omagnetic storm simulation, the total wall time is 256.29 hours on 5600 CPU cores.

573 We also introduced three physics based criteria to identify the reconnection regions  
 574 in the magnetotail. To demonstrate the feasibility of the MHD-AEPIC model, we have  
 575 performed a geomagnetic storm event simulation with kinetic physics embedded for the  
 576 first time. The flapping motion of the magnetotail current sheet during the geomagnetic  
 577 storm highlights the advantage of the adaptation feature of the MHD-AEPIC model.

578 We have also simulated the same event using Hall MHD and ideal MHD models  
 579 and compared the three models at multiple physical scales. We examined the global scale  
 580 features by comparing the SYM-H and SME indexes which reflect the equatorial and au-  
 581 roral region disturbances, respectively. All three models properly capture the global scale  
 582 disturbances such as the main phase of the storm or the increase of the auroral electro-  
 583 jet. However, all three models fail to produce the strongest intensity for the geomagnetic  
 584 indices. Hence no significant difference is found among the three different models at the global  
 585 scale for this event. This indicates that the global magnetosphere configuration from the  
 586 three models are very close, the kinetic model embedded in the magnetotail does not im-  
 587 prove the global scale feature for this geomagnetic storm. If this trend persists for other  
 588 storms, especially extreme events, is still to be investigated.

589 We analyze the mesoscale features by comparing the magnetic field components  
 590 and ion profiles between the Geotail observation and the simulations. All three models  
 591 show fairly good agreement with the Geotail observations, however, none of the three  
 592 models can match all features such as all the current sheet crossing or flux rope signa-  
 593 tures. The Hall MHD simulation shows more oscillations than observed during a few time

594 periods. In this storm event, MHD-AEPIC and ideal MHD models produce similar agree-  
 595 ment with the in-situ observations of Geotail.

596 In addition to comparing with the Geotail observations, we also compare the three  
 597 models with respect to flux rope structures in the current sheet. Only one major flux rope  
 598 can be observed from the ideal MHD simulation at the selected time, while Hall MHD  
 599 and MHD-AEPIC can produce flux ropes at a wider range in the dawn-dusk direction.  
 600 The difference of two types of the flux ropes: earth-ward with smaller spatial scale and  
 601 tail-ward with a larger spatial scale is also illustrated by the MHD-AEPIC simulations,  
 602 in agreement with several observations (Slavin et al., 2003).

603 The electron scale kinetic physics is well reproduced by the MHD-AEPIC model.  
 604 We collect electron macro-particle velocities at the same side of the electron diffusion  
 605 region as the MMS3 satellite did (Hwang et al., 2019). The velocity distribution func-  
 606 tions show excellent agreement between the simulation and the MMS3 observation. This  
 607 demonstrates that MHD-AEPIC can properly produce the electron scale features within  
 608 a single self-consistent global model while simulating a complete geomagnetic storm event.  
 609 In this particular simulation, including the kinetic reconnection physics does not improve  
 610 agreement with observations at meso- and global scales. This suggests that in this storm  
 611 event, the magnetosphere is mostly driven by the external solar wind and interplanetary  
 612 magnetic field and not by the internal reconnection dynamics.

613 It is to be investigated if the kinetic physics can have a more pronounced influence  
 614 on the physical condition of the magnetosphere when the external drivers are relatively  
 615 constant. Another important question is to compare the impact of kinetic versus numer-  
 616 ical reconnection during extreme events. In addition to studying the Earth's magneto-  
 617 sphere, we also expect the novel MHD-AEPIC model will find its applications in vari-  
 618 ous collisionless plasma systems that form small regions where kinetic effects are impor-  
 619 tant inside a large spatial domain.

## 620 Data Availability Statement

621 The Geotail data is publicly available at Data ARchives and Transmission System  
 622 (DARTS) of Institute of Space and Astronautical Science (ISAS) (<https://darts.isas.jaxa.jp>).  
 623 The MMS observation plot is acquired with consent from Dr. K.-J. Hwang (jhwang@swri.edu).  
 624 The SWMF code (including BATS-R-US and FLEKS) is publicly available through the  
 625 [csem.engin.umich.edu/tools/swmf](http://csem.engin.umich.edu/tools/swmf) web site after registration. The simulation output and  
 626 scripts used for generating figures in this paper can be obtained online through the Uni-  
 627 versity of Michigan's Deep Blue Data repository, which is specifically designed for U-  
 628 M researchers to share their research data and to ensure its long-term viability.

## 629 Acknowledgments

630 We thank Dr. Qusai Al Shidi at the University of Michigan for the script calculating the  
 631 SME index using interpolated virtual magnetometer data from BATS-R-US. This work  
 632 was primarily supported by NSF PRE-EVENTS grant No. 1663800. We also acknowl-  
 633 edge support from the NASA DRIVE Center at the University of Michigan under grant  
 634 NASA 80NSSC20K0600. We acknowledge the use of computational resources provided  
 635 by an NSF LRAC allocation at the Texas Advanced Computing Center (TACC) at The  
 636 University of Texas at Austin.

## Appendix A Reconnection due to numerical resistivity

It is a common practice to rely on numerical resistivity to mimic reconnection physics in global ideal and Hall MHD simulations. Analytic solutions of ideal MHD obey the frozen-in condition: the magnetic flux through a surface co-moving with the plasma (i.e. the ion fluid) does not change. For Hall MHD the magnetic flux is frozen into the motion of the electron fluid. A consequence of the frozen-in condition is that if two plasma elements are connected by a field line, then they remain connected forever, which means that magnetic reconnection cannot take place.

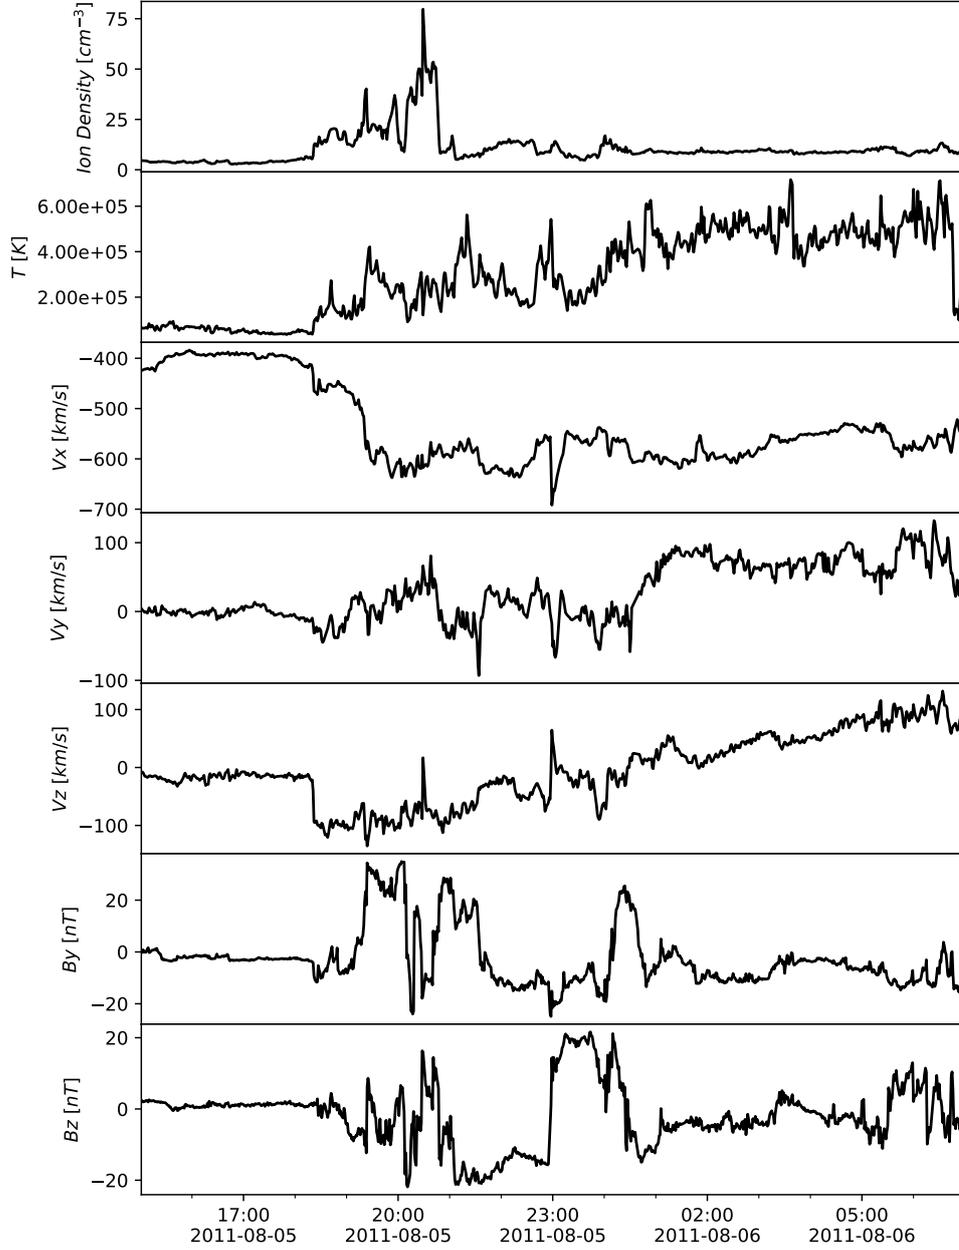

In reality, and also in the kinetic PIC model, the electrons and ions can “detach” from the magnetic field lines in the ion and electron diffusion regions, respectively. In effect, this allows the magnetic field lines to reconnect inside the electron diffusion region where the frozen in condition does not apply. The simplest mathematical description of this process is adding an Ohmic resistive term  $\eta \mathbf{j}$  into the induction equation:

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times [-\mathbf{u}_e \times \mathbf{B} + \eta \mathbf{j}] \quad (\text{A1})$$

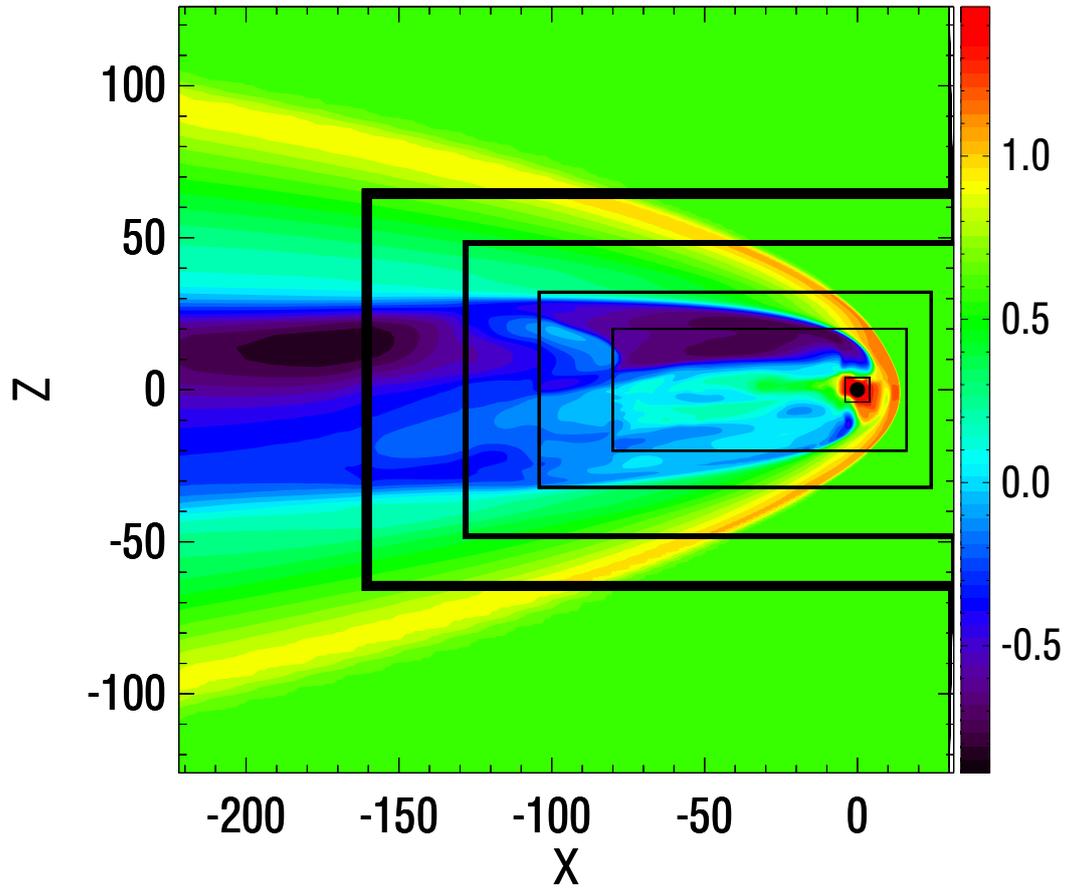

For constant resistivity  $\eta$  one can write this as

$$\frac{\partial \mathbf{B}}{\partial t} = -\nabla \times [-\mathbf{u}_e \times \mathbf{B}] + \eta' \nabla^2 \mathbf{B} \quad (\text{A2})$$

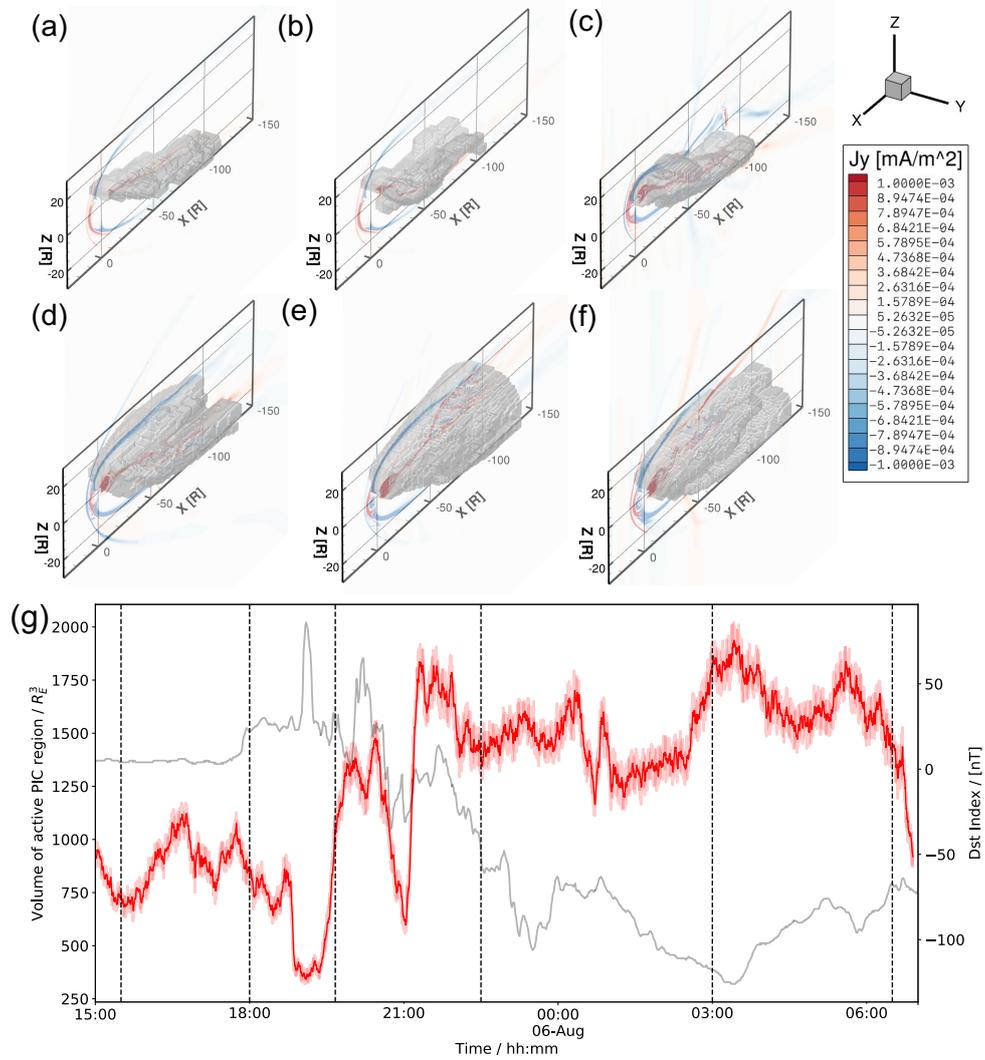

where we used  $\mathbf{j} = (1/\mu_0)\nabla \times \mathbf{B}$ , defined the magnetic diffusivity  $\eta' = \eta/\mu_0$  and exploited the divergence-free condition  $\nabla \cdot \mathbf{B} = 0$ . The usual argument in favor of using the ideal MHD model is that numerical resistivity will behave similarly to the diffusive term  $\eta' \nabla^2 \mathbf{B}$  and indeed, numerical experiments show that magnetic reconnection remains a robust feature of “ideal MHD” simulations. On the other hand, one would expect numerical diffusion to go to zero with increased grid resolution, which implies that reconnection should disappear from a well-resolved solution. In this appendix, we take a closer look and resolve this apparent contradiction.

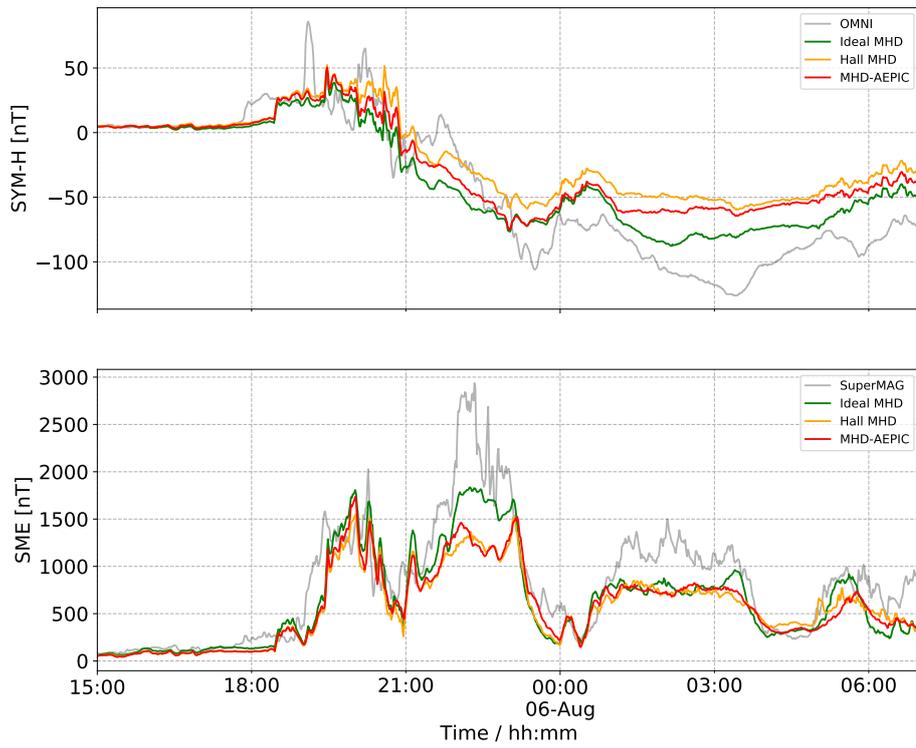

**Figure 2.** The solar wind bulk plasma and interplanetary magnetic field input in Geocentric Solar Magnetospheric coordinates (from top panel to the bottom: plasma density, plasma temperature,  $x$ ,  $y$  and  $z$  components of the plasma flow velocity,  $y$  and  $z$  components of the magnetic field) for the simulation in this paper. The  $x$ -component of the magnetic field is set to be 0. The solar wind data is obtained from the ACE spacecraft observation and propagated to the bow shock position (Pulkkinen et al., 2013).

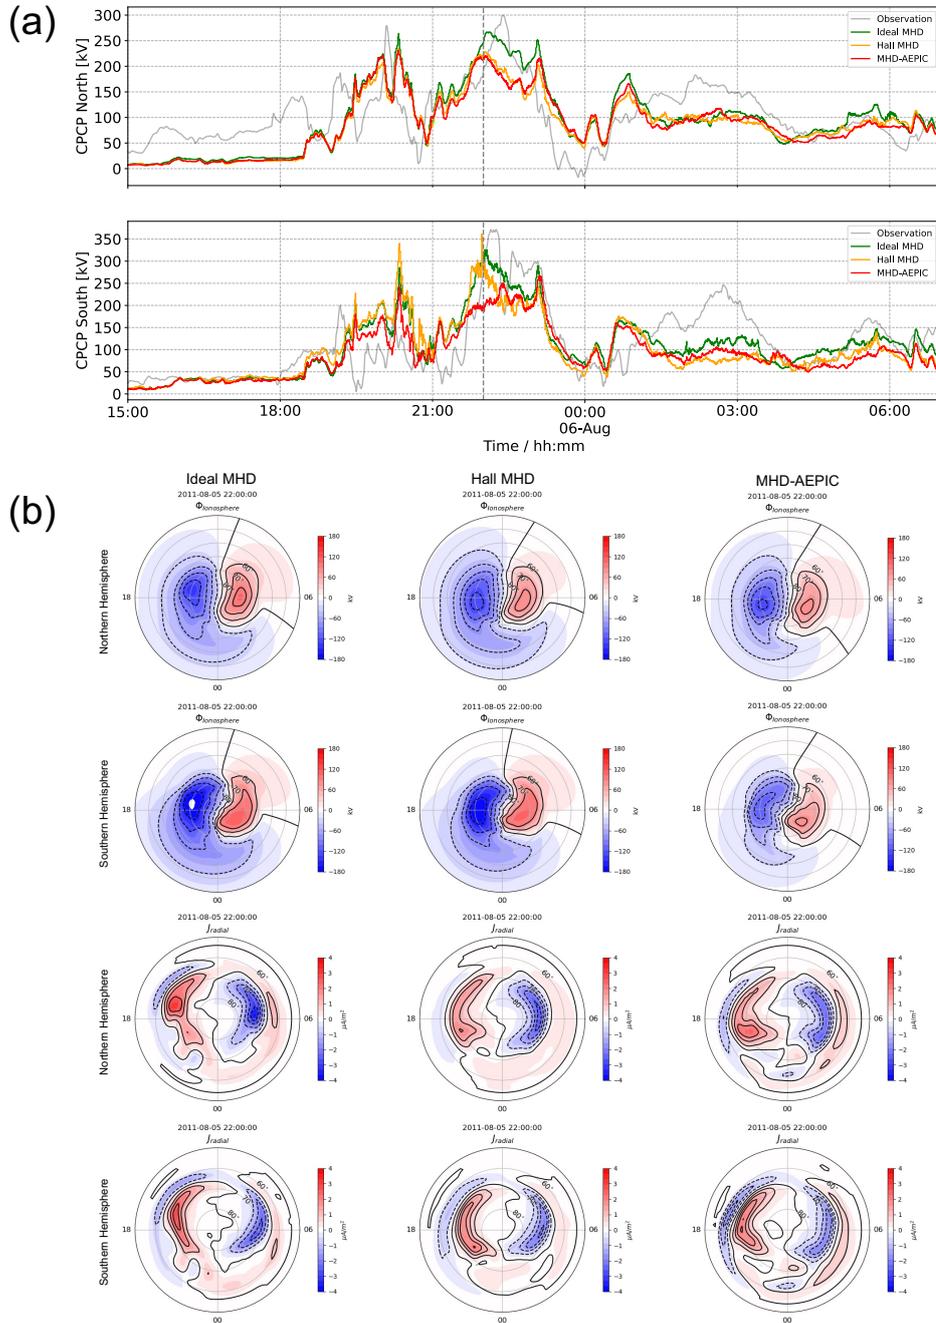

**Figure 3.** The meridional plane of the simulation domain. The color contour shows the plasma density of the steady state on a logarithmic scale. The black lines show the boundaries between different refinement levels. The refinement ratio between two adjacent levels is 2. The grid resolution near Earth is  $1/8 R_E$  it is  $1/4 R_E$  on the dayside and the magnetotail out to  $x > -80 R_E$ .

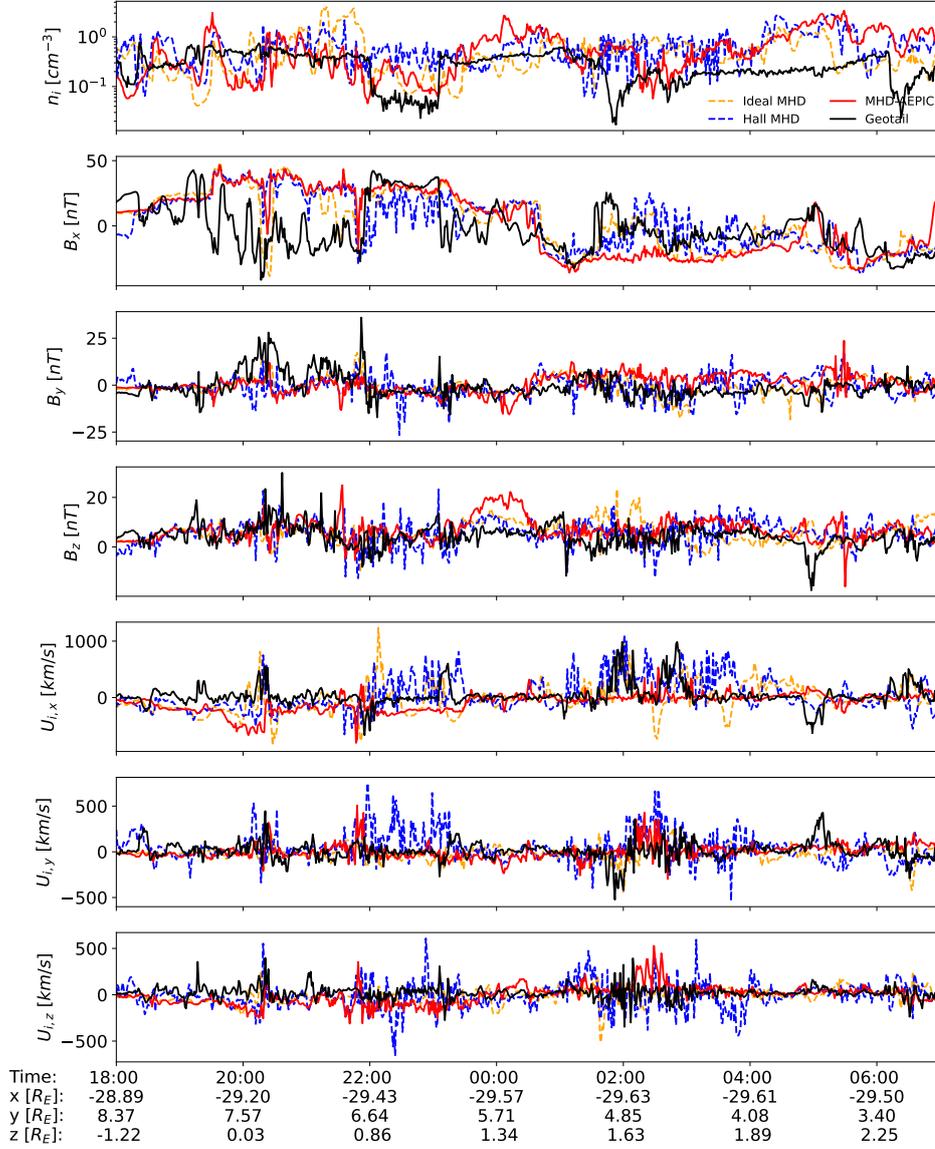

**Figure 4.** (a-f) Demonstration of PIC region adaptation during the simulation. The contour plot of  $j_y$  in the meridional plane is showing the general condition of the magnetospheric current system. The active PIC region boundary is shown by a gray isosurface. (g) Time evolution of the active PIC region volume. The translucent red line is the output every second and the solid red is the output smoothed every minute. The Dst index is plotted as a gray line for reference. The six vertical dashed lines correspond to the times of the snapshots (a)-(f), respectively.

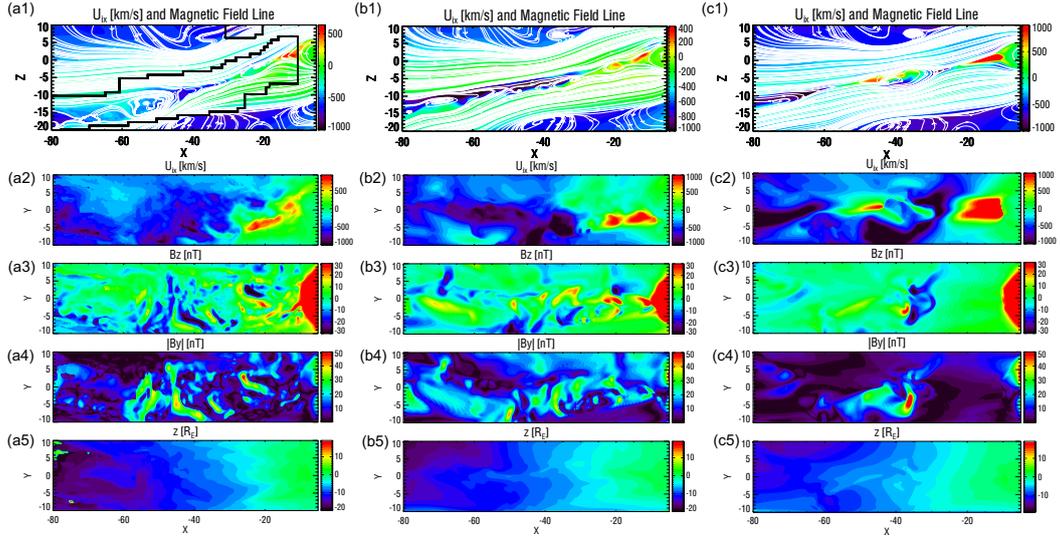

**Figure 5.** Aug. 6 2011 storm. Colored lines show the SYM-H and SuperMAG electrojet (SME) indexes from three different models and the gray line corresponds to the observed indexes.

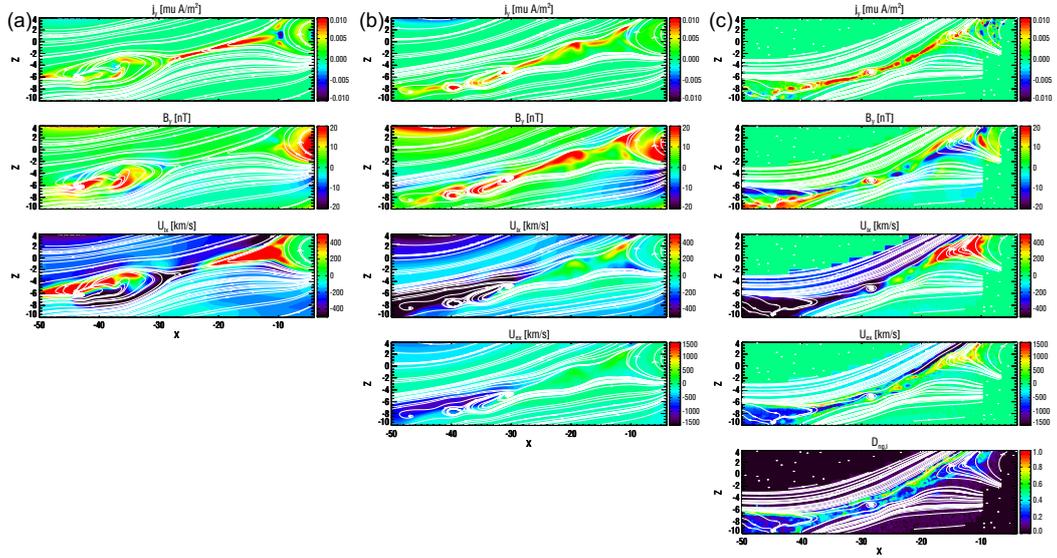

**Figure 6.** (a) The northern and southern cross polar cap potentials (CPCP) of the Aug. 6 2011 storm. Colored lines are model outputs, the gray line is the CPCP estimated (Ridley & Kihn, 2004) from the observed Polar Cap Index . (b) The northern and southern electric potentials and the radial current from the three models at 2011-08-05 22:00:00 (marked with a vertical dashed line in panel (a)).

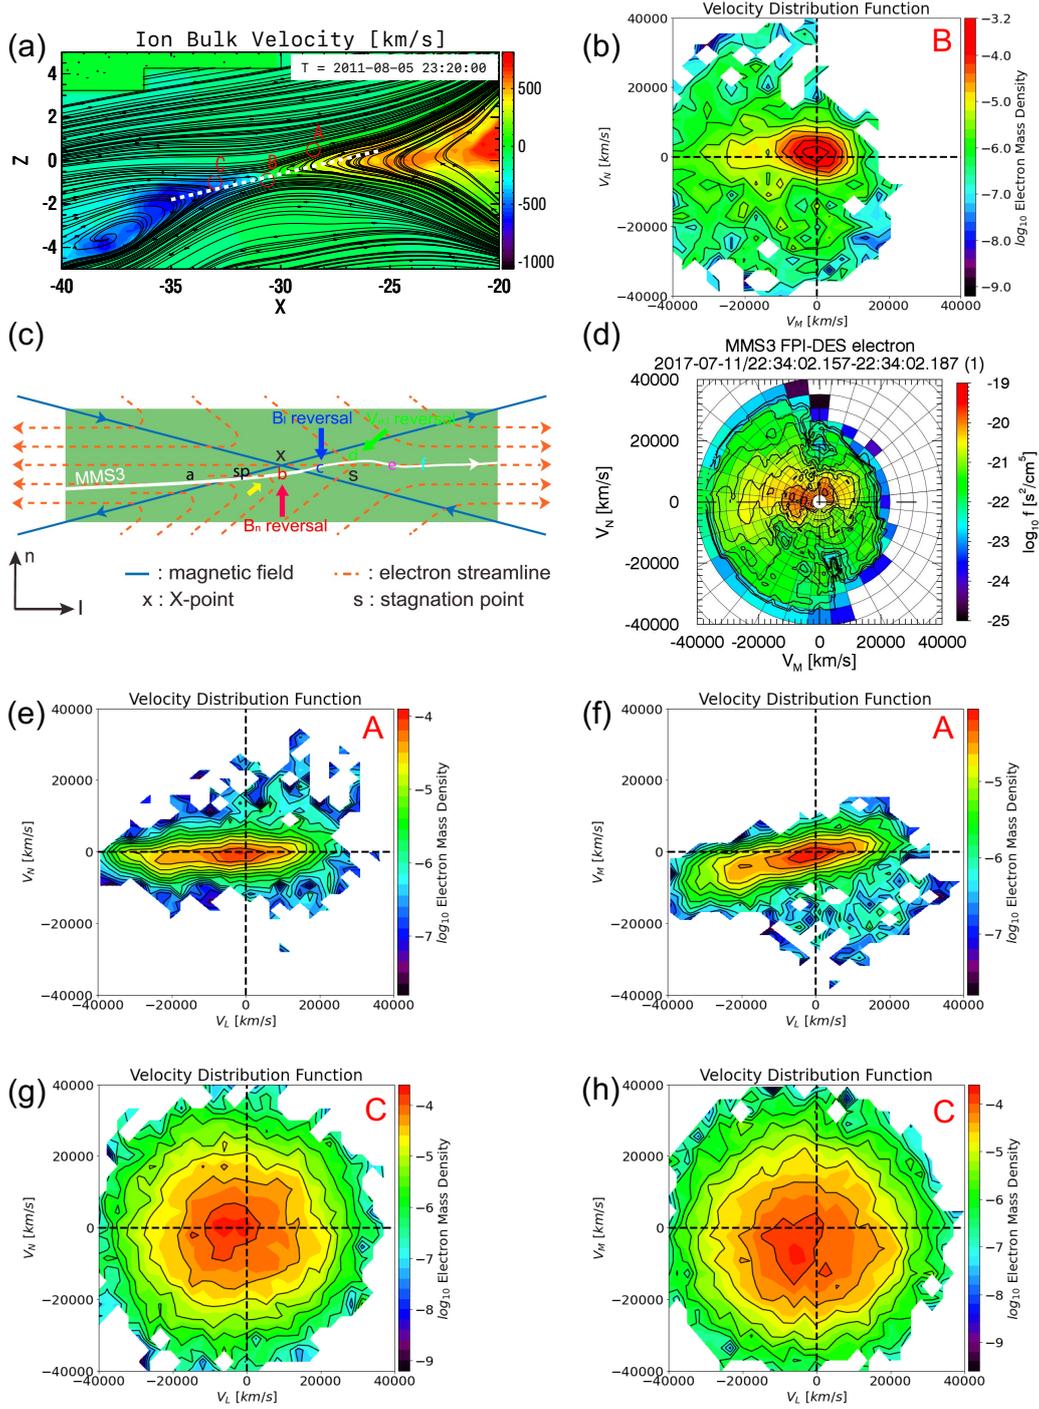

**Figure 7.** The ion density, magnetic field components and the ion velocity components observed by the Geotail spacecraft and the SWMF ideal MHD, Hall MHD and MHD-AEPIC simulations. The time interval shown starts from  $t = 2011-08-05$  18:00:00 right before the sudden commencement to  $t = 2011-08-06$  00:07:00 at the beginning of the recovery phase of the geomagnetic storm. The bottom X axis shows the GSE coordinates of the spacecraft at various times.

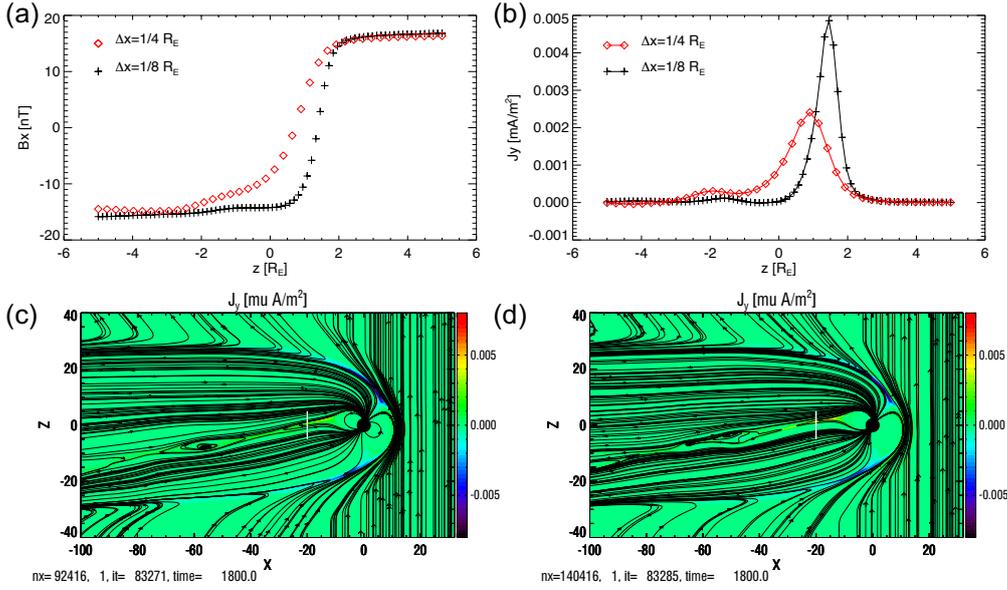

**Figure 8.** (a1) The  $x$  component of the ion bulk velocity  $u_{i,x}$  and magnetic field lines on the meridional plane from the MHD-AEPIC simulation. The black line shows the boundary of the active PIC region. (a2)  $u_{i,x}$  on the current sheet surface projected on the  $x$ - $y$  plane. (a3) The contour plot of the  $B_z$  on the current sheet surface, color saturated at  $\pm 30$  nT. (a4) The absolute value of  $B_y$  on the current sheet surface. A pair of positive and negative  $B_z$  along with a core  $B_y$  indicates a flux rope structure. (a5) The  $z$  coordinate of the current sheet surface in the unit of  $R_E$ . (b1)-(b5) are same quantities from the Hall MHD and (c1)-(c5) are from the ideal MHD simulation. All snapshots are taken at the same time 2011-08-05 19:40:00.

**Figure 9.** (a) The current density  $j_y$ , out-of-plane magnetic field  $B_y$  and ion bulk velocity in the  $x$  direction  $U_{ix}$  from the ideal MHD model near the reconnection X-line. (b) Same physical quantities as panel (a) from the Hall MHD model with an extra electron bulk velocity in the  $x$  direction  $U_{ex}$  calculated from the current. (c) Same physical quantities as panel (b) from the MHD-AEPIC model with an extra ion nongyrotropy measure  $D_{ng,i}$  defined by Aunai et al. (2013). The area covered by the magnetic field lines is the active PIC region.

**Figure 10.** (a) The contour plot of the ion bulk velocity overplotted with magnetic field lines. The 2D cut is taken on the meridional plane. The three red circles are the position where the electrons for the VDF are collected. A: Inflow region, B: Electron Diffusion Region, C: Outflow region. The white dashed line with a Notice that some area at upper left is not covered by PIC which illustrates the AEPIC feature. (b) The electron VDF from the simulation, colored in electron mass density in log scale. (c) A sketch (Figure 1 (b) in Hwang et al. (2019)) demonstrating possible magnetic field geometries. The white curve represents a possible MMS3 trajectory. The electron VDF in (d) is taken at the position *b* pointed by a red arrow. (d) MMS3 observation (Figure 2 (c) in Hwang et al. (2019)). (e)-(f) The electron VDF taken at the inflow region. (g)-(h) The electron VDF taken at the outflow region.

**Figure 11.** (a) The  $B_x$  profiles across the current sheet from two simulations with different grid resolutions in the magnetotail. The profiles are taken along the  $x = -20 R_E$  and  $y = 0$  line from  $z = -5 R_E$  to  $5 R_E$ . The symbols show the discrete values at the grid cell centers. (b) The  $J_y$  current profiles taken at the same position as  $B_x$  in panel (a). (c) The meridional cut of the simulation domain with  $J_y$  and magnetic field lines for  $1/4 R_E$  grid resolution in the magnetotail. (d) Same physical quantities as panel (c) but with  $1/8 R_E$  grid resolution in the magnetotail.

887 The main argument is that an ideal MHD reconnecting current sheet behaves like  
 888 a discontinuity and therefore the derivatives of the solution across the current sheet do  
 889 not converge to a finite value. In particular, the current density, obtained from the deriva-  
 890 tive of the magnetic field, goes to infinity as the grid resolution is increased, while the  
 891 numerical diffusion goes to zero. Their product, which determines the reconnection rate,  
 892 remains finite. The global reconnection rate in the magnetosphere, in fact, is mostly set  
 893 by the external conditions. On the dayside, the solar wind brings in magnetic flux at a  
 894 rate of  $|u_x|B_z$ . A fraction of this flux will reconnect at the dayside magnetopause for  $B_z <$   
 895  $0$ . Since the magnetic flux attached to the Earth cannot grow without bound, there has  
 896 to be a matching reconnection rate in the magnetotail, which completes the Dungey cycle.  
 897 This means that the global time averaged reconnection rate is predominantly set by  
 898 the external solar wind and IMF driver, and not by the details of the physics at the re-  
 899 connection sites (Gonzalez et al., 2016).

900 We now look into more detail, how the numerical scheme actually achieves this. For  
 901 finite volume methods solving the

$$\frac{\partial U}{\partial t} + \nabla \cdot F = 0 \quad (\text{A3})$$

902 equation, the numerical flux is calculated at the cell interfaces, and it depends on the  
 903 right and left states  $U^R$  and  $U^L$  extrapolated from the right and left directions, respec-  
 904 tively, and the characteristic wave speeds. The Lax-Friedrichs flux is the simplest ex-  
 905 ample:

$$F^{LF} = \frac{F(U^R) + F(U^L)}{2} - \frac{1}{2} \lambda_{\max}(U^R - U^L) \quad (\text{A4})$$

906 where  $F$  is the physical flux function. The first term contains the physical flux as the av-  
 907 erage of  $F(U^R)$  and  $F(U^L)$ . The second term introduces numerical diffusion to preserve

908 the monotonicity of the numerical solution. The numerical diffusion is proportional to  
 909 the fastest wave speed  $\lambda_{\max}$  corresponding to the fast magnetosonic wave in ideal MHD.  
 910 The  $U^R - U^L$  difference is some fraction of the difference between the cell center val-  
 911 ues on the two sides of the cell:

$$(U^R - U^L)_f = \alpha_f(U_{k+1} - U_k) \quad (\text{A5})$$

912 Here  $f$  represents the index of the cell face between cells indexed by  $k$  and  $k+1$ . The  
 913 fraction  $0 \leq \alpha_f \leq 1$  depends on the numerical scheme. For a first order scheme  $\alpha_f =$   
 914 1. For a higher order scheme, the fraction depends on the limiters used in the algorithm  
 915 and the differences of  $U$  in neighboring cells.

916 For sake of simplicity, let us consider a current sheet parallel to the  $X$ - $Y$  plane  
 917 and assume that  $B_x$  changes sign across the current sheet as we move in the  $Z$  direction.  
 918 The physical flux function in the  $Z$  direction is  $F = v_z B_x - v_x B_z$ . The numerical flux  
 919 function at the cell interface  $f$  is

$$F_f^{LF} = \frac{F(U_f^R) + F(U_f^L)}{2} - \frac{1}{2} \lambda_{\max, f} \alpha_f (B_{x, k+1} - B_{x, k}) \quad (\text{A6})$$

920 The numerical diffusive part of the flux can be written as

$$F_f^{\text{diff}} = - \frac{\lambda_{\max, f} \alpha_f \Delta z}{2} \frac{B_{x, k+1} - B_{x, k}}{\Delta z} \quad (\text{A7})$$

921 which is a numerical approximation of  $\eta' \partial_z B_x$  with the numerical diffusivity

$$\eta' = \frac{\lambda_{\max, f} \alpha_f \Delta z}{2} \quad (\text{A8})$$

922 For a smooth solution  $\partial_z B_x$  converges to a finite value as the grid is refined, while  $\eta'$  con-  
 923 verges to zero because  $\Delta z \rightarrow 0$ . For a discontinuous solution, however, the difference  
 924  $B_{x, k+1} - B_{x, k}$  as well as  $\lambda_{\max, f}$  and  $\alpha_f$  all become independent of the grid resolution  
 925 as  $\Delta z \rightarrow 0$ . This is a direct consequence of the fact that neither the ideal MHD equa-  
 926 tions, nor the numerical scheme has any intrinsic length scale other than the grid cell  
 927 size. This means that the current sheet will be resolved with a fixed number of grid points  
 928 following a fixed numerical profile (a series of the discrete values  $B_{x, k}$  across the current  
 929 sheet) independent of the grid resolution for small enough  $\Delta z$ . Therefore the numeri-  
 930 cal reconnection rate will converge to a finite value, determined predominantly by the  
 931 external conditions (the external field  $B_x^{\pm \text{ext}}$  and the converging velocity  $u_z^{\pm \text{ext}}$  outside  
 932 the current sheet), instead of zero. In physical terms, the numerical resistivity  $\eta'$  goes  
 933 to 0, but the current density  $(1/\mu_0) \Delta B_x / \Delta z$  goes to infinity and their product remains  
 934 finite.

935 The maximum possible numerical reconnection rate is  $\lambda_{\max, f} |B^{+\text{ext}} - B^{-\text{ext}}|/2$   
 936 corresponding to a current sheet where the magnetic field jumps from  $B_x^L = B_{x, k} =$   
 937  $B_x^{-\text{ext}}$  to  $B_x^R = B_{x, k+1} = B_x^{+\text{ext}}$  across a single cell face, and  $\lambda_{\max, f}$  is the maximum  
 938 (or average) of the fast magnetosonic speeds taken at the two cell centers next to the  
 939 face. The fraction  $\alpha_f$  is 1 at this interface independent of the nominal order of the scheme,  
 940 because all schemes drop to first order at this type of numerical discontinuity due to the  
 941 limiters. This maximum numerical reconnection rate far exceeds the typical physical re-  
 942 connection rate  $\approx 0.1 v_A |B^{\text{ext}}|$ , where  $v_A$  is the Alfvén speed, found in PIC simulations.  
 943 The actual numerical profile realized by the numerical scheme will have multiple points  
 944 across the current sheet resulting in a lower numerical diffusion rate than the theoret-  
 945 ical maximum. In a 2 or 3 dimensional system, the global reconnection rate will depend  
 946 on many factors, including the presence of Hall physics, which has a major impact on  
 947 the structure of the reconnection site (Birn et al., 2001) and the achievable reconnec-  
 948 tion rate.

949 Figure 11 shows that these theoretical consideration are indeed valid in a compli-  
 950 cated 3D magnetosphere simulation. We have performed two ideal MHD simulations with

951  $\Delta x = 1/4 R_E$  and  $1/8 R_E$  grid resolutions in the magnetotail, respectively. We com-  
952 pare the numerical solution across the current sheet at the same place and same time.  
953 As the figure shows, the number of grid cells, represented by the symbols, across the cur-  
954 rent sheet and the magnetic field values at the cell centers are essentially the same in  
955 the two simulations. The only change is the physical distance between the cells, which  
956 is reduced by a factor of 2 on the finer grid. As a result, the current density is twice higher,  
957 while the numerical dissipation rate is half of those obtained on the coarser grid. In the  
958 end, the reconnection rate is essentially the same in the two simulations, which results  
959 in essentially the same global solution.
