1.   Data coverage

Seismic ambient noise data in this study are recorded by 69 broadband stations belonging to 6 different seismograph networks (Table S1). Maps of crossing raypaths for the final processed data sets at all 20 periods used in the tomography are presented in Figure S1. Phase velocities are estimated over a grid of 212 nodes and variations of the azimuthal coverage and path density parameters over the inversion grid are provided in Figures S2-S3. Calculation of path density at the nodes was done by checking if great-circle points separated by 5 km along the rays lie within a 50 km radius around the inversion nodes for the available rays (Figure S2). To assess the azimuthal distribution of the paths, the 50 km radius around each inversion node was divided into 5 degree bins, and the number of bins containing 1 or more rays was counted to calculate the percentage azimuthal coverage (Figure S3).

2.   Data set statistics

Figure S4 illustrates statistics for all the measured Empirical Green's Functions (EGFs), all phase velocity (dispersion) measurements, and phase velocities used in the final tomography model. The final phase velocity measurements that were input to the tomographic inversions are limited by both a minimum signal-to-noise ratio (SNR) threshold and vari-

able minimum inter-station distance threshold for each period. The minimum SNR threshold for the EGFs was calculated using the formula $\mu - 2\sigma$, where μ is the mean and σ is the standard deviation, for the symmetrized SNR distribution, resulting in a value of 8.8 dB for the final data sets (Figure S4a). The minimum inter-station distance threshold varies for different periods and it is calculated using the formula $\Delta \geq 3\lambda$, where Δ is the interstation distance and λ is the characteristic wavelength measured by multiplying average velocity (km/s) by period (s) for different periods (purple dashed lines in Figure S4b-f).

3.   Tomography regularization

The final smoothing and damping values (regularization parameters; Table S2) were decided based on the trade-off curves (model roughness versus data fit; a better fit corresponds to a lower "remaining variance") and visual assessment of the output phase velocity maps. The trade-off curves for the 2ψ and 4ψ surface wave components along with examples of the pertinent phase velocity maps are presented in Figures S5-S6 (see main paper for the isotropic component).

4.   Resolution tests

The main influencing parameters on the resolving power of a tomography method include the data coverage (Figures S1-S3), and the inversion regularization parameters (Table S2). To assess the resolution of the phase velocity maps, we present the results of resolution tests at four representative periods of 6, 14, 25, and 40 s.

In addition to the spike tests that are discussed in the main paper, we also conducted four extra spike tests, with no anisotropy, in the form of stripe patterns (Synthetic models

September 14, 2021, 10:09am

S1-S4; Figure S7). These stripes are along two different directions (S1-S2 along NE-SW, and S3-S4 along NW-SE), and with two widths of 80 km (S2 and S4; similar to the inversion node spacing) and 240 km (S1 and S3). The results for the wider stripes suggest an almost perfect recovery at all periods with some very small reduction of amplitude recovery with increasing period. Recovering the narrower 80 km stripes is, however, more challenging for the tomography. The amplitudes of the anomalies across the Gulf of Saint Lawrence, and in the north, are greatly reduced. Anomaly smearing is observable in the north, and also across the Gulf of Maine, especially evident for the NW-SE trending model S4. Spurious anisotropy is limited to the regions close to the edge of the study area, and it is more evident for the narrow stripes (maximum $\sim$1%).

Two sets of linear gradient resolution tests, with no anisotropy, are carried out along NW-SE (model G1) and NE-SW (model G2) directions (Figure S8). Due to the aperture of the study area and differences of data quality along different paths, anomaly patterns elongated along a certain direction might be better recovered, and linear gradient resolution tests are useful to reveal such observations. Comparing the resolving power for models G1 and G2, they are similarly recovered at the shorter periods (6-12 s), but more oscillatory distortion of the linear features is observed in model G2 than model G1 at longer periods (25-40 s). Some small spurious anisotropy ($<$1%) is observable near the northeast and southern edges of the study area (Gulf of Saint Lawrence and Gulf of Maine).

Surface wave velocity inversions include trade-offs between the isotropic and anisotropic components. In order to estimate the amount of leakage between the isotropic and anisotropic components, we conducted leakage tests by inputting only one component of the final phase velocity model and recovering all the surface wave components (Figures

S9-S10). If the inversion of surface wave velocity was perfectly ideal, the inversion would recover the full input signal (e.g., 2ψ anisotropy only) without any signals for the other surface wave components (e.g., isotropic and 4ψ). Examining the results of these tests are helpful for identifying robust model features, and avoiding overinterpretation. In general, the results of these tests suggest a small leakage between the surface wave velocity component and with a generally increasing effect observable with increasing period. Our observations from these tests are listed below:

• Using only isotropic velocity structure as the synthetic input model (second column in Figures S9-S10), the results at all periods suggest that the patterns of isotropic variations are well-recovered, and anisotropy output (2ψ and 4ψ) is very small. That said, we observe loss of amplitude for the anomaly in the North (centred at 73°W, 48.5°N) at 14-25 s period.

• Using only the 2ψ anisotropy component as the input model (third column in Figures S9-S10), the inversion produces very similar pattern and magnitude of 2ψ anomalies at all periods, and the leakage effect for the 4ψ and isotropic components stays mostly minimal. We observe some spurious isotropic anomaly across northeastern Nova Scotia, and near the northern and southern edges of the study area. Some small spurious 4ψ anomalies are also observable beneath Nova Scotia and across the Gaspé Peninsula at the longer periods (25-40 s).

• Lastly, using only the 4ψ anisotropic velocity heterogeneity as the input model (right column in Figures S9-S10), the inversion recovers the 4ψ variations very well at all periods. Compared to the 2ψ input only tests, the observed spurious isotropic anomalies occur beneath similar regions, but this time they are noticably smaller. Spurious 2ψ signals are

mainly observed across Nova Scotia (6-40 s), beneath the Gulf of Maine (40 s), in the southeast (25-40 s), and the northwest of the study area (25-40 s).

To futher examine the resolution of our anisotropic velocity model, we rotated the final 2ψ inversion output by 90° and used it along with the original isotropic solution as the synthetic input models. Figure S11 presents the results of this test at the four representative periods. The inversion produces very similar output at 06-25 s period, whereas the recovered patterns at 40 s period do not match very well with the input model across the Gulf of Saint Lawrence, and the Gulf of Maine. These two regions are subject to low path density and azimuthal coverage (Figures S2-S3).

5.   Phase velocity maps

We obtained reliable phase velocity measurements at periods between 4 s and 50 s from the generated EGFs. The full set of phase velocity maps at these periods are presented in Figures S12-S13.

6.   Shear velocity model

Our pseudo-3D shear wave velocity model was constructed from the inversions of the 1D local dispersion curves extracted from the 212 inversion nodes of the phase velocity maps. The resulting shear wave velocity maps at a selection of depths from 1 km to 80 km are presented in Figures S14-S16. We also estimated the Moho depths and thicknesses across the study area using two different proxies (Figure S17). Moho depth locations are calculated by locating the 50% and 85% increase values from typical crustal velocities (at 15-25 km depth) toward typical mantle velocities (at 55-65 km depth) for the 1D shear velocity profiles used to make the final shear velocity maps.

7. Effect of non-uniform noise distribution

Previous ANT studies have mentioned the importance of noise distribution in the reliability of phase velocity measurements (e.g., Bensen et al. 2007). Since the main pre-assumption in the ANT method is that the ambient seismic noise recorded across the study area should be uniformly distributed, a non-uniform noise distribution could cause the resulting models to be biased, and therefore unreliable (e.g., Tian & Ritzwoller 2015, Yang et al. 2008). The main sources of ambient seismic noise generation are believed to be in the oceans (e.g., Gutenberg 1936). Therefore, the seismic noise distribution for study areas located near coastlines can show significant directional bias due to their geographical position. As our study area likely receives the strongest seismic noise from the nearby Atlantic ocean (Figures 1-2 in the main paper), we designed a test procedure to quantify the effect of non-uniform seismic noise distribution in the measurements of phase velocities.

It is suggested that the measurement bias for EGF data sets with a sufficiently smooth non-isotropic noise distribution is small (e.g., Weaver et al. 2009). The best data coverage in our study area is only provided in the 2013-2015 time window as used in this study (Section 2.1 in the main paper), limiting our investigation of different data set scenarios for finding the smoothest varying non-isotropic noise data. According to our tests, however, a stack number of about 6 months for the noise correlation functions is enough for producing reliable EGFs (Figure S18). With the aim of generating a semi-homogenous collection of EGFs that experience a much weaker directional bias than that observed in the final data sets, we processed 12 different seasonal EGF data sets that were created using different 6 month stacks of noise correlation data. We investigated the signal strength coming from

different directions by calculating SNR values of both causal and acausal signals averaged over 5° azimuthal bins for all the 12 different generated seasonal data sets, and considered a few different statistical parameters for the calculated variations to find out which one of the seasonal data sets suggests the smoothest non-isotropic noise distribution (Figure S19). We found that the EGFs resulting from stacking over the months of May-July (2 sets of 3-month stacks) show the smoothest directional variations; hereafter we call the this data set the "semi-homogenous" data set. Table S3 shows the subjective criteria for our decision of choosing the semi-homogenous data set based on the calculated statistical parameters.

We measured all possible inter-station dispersion curves using the same method and procedure used to measure the dispersion data sets that were input to the final phase velocity model inversions (Sections 2.2 and 2.3 in the main paper). We then extracted only paths that were common between the semi-homogenous and final data sets from the measurements to eliminate the effect of variable path coverage between the two data sets. Therefore, if we invert the two new data sets to obtain results, we should recover similar phase velocity maps at each period. Any difference between the recovered phase velocities at the same period can thus be attributed to the effect of non-isotropic noise distribution in the data. Although this test does not fully quantify the effect of the directional bias in our study (because the semi-homogenous data is not an absolutely homogenous data set), it still gives an acceptable estimation for the non-uniform noise distribution effect.

Figure S20 shows the inversion results for the semi-homogenous and final data sets with the same path coverage at different representative periods. As suggested by this illustration, the main model features are generally well-recovered in both models and

most of the differences occur in areas where the path coverage is not sufficient (e.g. Gulf of Saint Lawrence, and areas on the edge of the path coverage). We find the non-uniform noise distribution effect minimal, generally lower than 0.05 km/s, for periods < 30 s. This range is similar to the range of phase velocity uncertainties, and therefore too small to affect the interpretation of our models. For the longer periods that are mostly sensitive to mantle depths, the difference becomes more considerable (0.1-0.2 km/s), especially in regions with less-ideal path coverage such as areas close to the edges of the phase velocity maps including near the Newfoundland coast, northern Nova Scotia, and Gulf of Maine. In the centre of the study area where the path coverage is the best at all periods, the effect of directional bias stays minimal even for the longest periods (Figure S20). This suggests the underappreciated importance of a sufficient path-coverage in removing the effect of directional bias in the measurement of phase velocity maps in ANT studies. Finally, despite being located in a region that is significantly affected by noise directional bias, we conclude that our final phase velocity measurements are reliable. That said, we note that the resolution test results and maps of path coverage at different periods must be considered in the final interpretations of the observed model features.
