## Key Points:

- Full-waveform inversion models enable the use of shorter-period data in earthquake source inversion.
- Using regional waveforms at 15 s period may reduce non-double-couple components by tens of percent.
- Probability densities of source parameters below 20 s are non-Gaussian, thus demanding stochastic inversion approaches.

---

**Abstract**

We present probabilistic centroid-moment tensor solutions inferred from the combination of Hamiltonian Monte Carlo sampling and a 3-D full-waveform inversion Earth model of the Japanese archipelago. While the former provides complete posterior probability densities, the latter allows us to exploit waveform data with periods as low as 15 s. For the computation of Green’s functions, we employ spectral-element simulations through the radially anisotropic and visco-elastic model, leading to substantial improvements of data fit compared to layered models. Focusing on  $M_w$  4.8 –  $M_w$  5.3 offshore earthquakes with a significant non-double-couple component, we simultaneously infer the centroid location, time and moment tensor without any a priori constraints on the faulting mechanism. Furthermore, we perform the inversions across several period bands, varying the minimum period between 15 s and 50 s. Accounting for 3-D Earth structure at shorter periods can increase the double-couple component of an event, compared to the GCMT solution, by tens of percent. This suggests that at least some of the non-double-couple events in the GCMT catalog might result from unmodeled Earth structure. We also observe that significant changes in source parameters, and the double-couple component in particular, may be related to only small waveform changes, thereby accentuating the importance of a reliable Earth model. Posterior probability density distributions become increasingly multimodal for shorter-period data that provide tighter constraints on source parameters. This implies, in our specific case, that stochastic approaches to the source inversion problem are required for periods below  $\sim 20$  s to avoid trapping in local minima.

**Plain Language Summary**

In the majority of global earthquake catalogs, the earthquake solution, i.e., centroid location, time and a rupture mechanism, is typically inferred assuming a 1-D Earth model. However, both earthquake source and Earth structure contribute to seismic recordings, meaning that unaccounted structure might map into and pollute the source solution. In this study we use a 3-D Earth structure of the Japanese archipelago to model the waveforms and infer earthquake parameters of small-to-moderate magnitude offshore events. We do not put any a priori constraints on the faulting mechanism and let it be determined by the data. We perform stochastic inversions which provide us with a collection of all plausible models ranked by their respective probability. When a 3-D Earth structure at shorter periods is taken into account, the earthquake mechanism can be largely explained by a slip on the fault. We also observe that significant changes in source parameters may be related to tiny waveform changes, thereby accentuating the importance of a reliable Earth model.

**1 Introduction**

Earthquake source solutions are important in many fields of seismology, such as, but not limited to, seismic hazard, earthquake physics, seismotectonics, and seismic tomography. Although source inversion is an established discipline in seismology, obtaining a robust solution of moment tensor components together with a spatial and temporal location is still a challenging task. A largely unexplored potential lies in the adoption of more realistic Green’s functions, which until recently have only accounted for radially symmetric Earth structure. In the wake of increasing computational power and growing number of full-waveform tomographic models, use of numerically computed Green’s functions for complex regional Earth models has become possible.

## 1.1 Recent developments in source inversion

Earthquake source mechanisms, in terms of the first-motion polarities and fault-plane solutions, have been studied since the beginning of the 20th century (Omori, 1905; Galitzin, 1909; Byerly, 1928), and the first computer programs, intended to aid the graphical analysis, were developed in the early 1960s (Knopoff, 1961; Kasahara, 1963). A significant development was accomplished by Backus and Mulcahy (1976a, 1976b), who derived a phenomenological representation for an indigenous source and showed that each seismic source can be described by a moment tensor, or a distribution thereof. Seismic source inversion has become routine since the end of the last century (e.g., Mendiguren, 1977; Kanamori & Given, 1981; Dziewoński et al., 1981). Since then, different approaches have been established to retrieve information on the source parameters, based on, e.g., first-motion polarity (e.g., Knopoff, 1961; Kasahara, 1963; Lentas, 2017; Hara et al., 2019), body waveforms (e.g., Dziewoński et al., 1981; Dreger & Helmberger, 1991; Vallée et al., 2011), surface waves (e.g., Kanamori & Given, 1981; Romanowicz, 1982; Ferreira & Woodhouse, 2006), with a specific interest to the ultra-long-period W-phase (e.g., Kanamori & Rivera, 2008; Duputel et al., 2012; Hayes et al., 2009), or full waveforms, incorporating both body and surface wave signals (e.g., Dreger, 2003; Ekström et al., 2012; Scognamiglio et al., 2016; Hallo et al., 2017). While some methods might be more robust than others, all of them, to some degree, rely on how well one can predict the data for a given set of model parameters. The choice of the Earth model, hence, is of fundamental importance in earthquake source inversion, as unaccounted Earth structure might map into the source solution and potentially pollute it (e.g., Hjörleifsdóttir & Ekström, 2010; Woodhouse, 1983; Smith & Ekström, 1996; Thurber, 1983).

Until recently, radially symmetric Earth models have been predominantly used in source inversion studies, for they allow one to efficiently compute Green's functions. Lateral heterogeneities are then taken into account via empirical or theoretical corrections (Ferreira et al., 2011). For example, traces or even the different portions of Green's functions can be shifted independently to fit the data (e.g., Zhao & Helmberger, 1994; Zhu & Helmberger, 1996; Ford et al., 2009a, 2009b). However, such corrections might mask earthquake source effects. Theoretical surface wave corrections may be implemented in terms of mean phase slowness along the source-receiver great circle (e.g., Woodhouse & Dziewoński, 1984; Pondrelli et al., 2002), neglecting the amplitude effects. In addition, great circle approximations, relying on ray theory, do not account for finite-frequency effects of wave propagation, hence the corrections themselves might be erroneous. Another approach is to use multiple 1-D Earth models to account for differences in oceanic and continental crust (Lee et al., 2011), as is done for the National Research Institute for Earth Science and Disaster Prevention (NIED) earthquake catalog in Japan (Kubo et al., 2002). Alternatively, the dependence on structural models can be alleviated, focusing on those data which are less sensitive to crustal heterogeneities, such as the W-phase (Kanamori & Rivera, 2008) or the Pnl phase (Helmberger & Enge, 1980).

With increasing computational power, improving numerical methods (e.g., Nissen-Meyer et al., 2007; Komatitsch et al., 2010; Krischer et al., 2015; Gokhberg & Fichtner, 2016; Afanasiev et al., 2018) and theoretical developments (e.g., Tromp et al., 2005; Fichtner, van Herwaarden, et al., 2018; Thrastarson et al., 2020; van Herwaarden et al., 2020), full-waveform tomographic models have been proliferating on both regional (e.g., Fichtner et al., 2009a; Krischer et al., 2018; Blom et al., 2020) and global scale (e.g., Bozdağ et al., 2016; French & Romanowicz, 2014; Fichtner, van Herwaarden, et al., 2018). This has in turn enabled researches to start using numerically computed 3-D Green's functions for source inversion. Such type of studies have been performed for the Southern California region (Liu et al., 2004; Zhao et al., 2006; Lee et al., 2011; X. Wang & Zhan, 2019), the Australian region (Hingee et al., 2011; Hejrani et al., 2017), the Sichuan province in China (Zhu & Zhou, 2016) and more recently for offshore earthquakes along the Nankai trough in Japan (Takemura et al., 2018, 2020).

114 The non-linear relationship between data and model parameters, such as centroid  
 115 location and centroid time of an earthquake, make it difficult to tackle the source inver-  
 116 sion with deterministic approaches. The least-squares method, for example, provides a  
 117 single solution and does not account for non-uniqueness, which can arise due to insuf-  
 118 ficient data coverage and modeling inaccuracies. Furthermore, uncertainty information,  
 119 derived by linearization methods, is only representative if the objective functional is in-  
 120 deed quadratic or otherwise have little meaning at all (Sambridge & Mosegaard, 2002).  
 121 To tackle these challenges, we resort to probabilistic inference, which provides a collec-  
 122 tion of all plausible models ranked by their respective probability. Statistical inferences  
 123 can be made from the ensemble to assess the uncertainty, and covariance matrices can  
 124 be recovered to study the inter-parameter trade-offs. Such an approach respects the non-  
 125 uniqueness, avoids the subjective regularization required by the deterministic inversion,  
 126 and delivers uncertainty measures as part of the solution. However, a more vigorous ex-  
 127 ploration of the model space typically comes with higher computational costs.

128 Stochastic approaches were used in the inversions of microseismic events (e.g., Pugh  
 129 et al., 2016; Shang & Tkalčić, 2020), of events with anomalously high non-double-couple  
 130 component (e.g., Mustać & Tkalčić, 2016), finite-fault inversions (e.g., Minson et al., 2014;  
 131 Duputel et al., 2014; Dettmer et al., 2014), and for earthquake early warning purposes  
 132 (Cua & Heaton, 2007). Only a few probabilistic studies have been performed using fully  
 133 heterogeneous Earth models (e.g., Lee et al., 2011).

## 134 1.2 Hamiltonian Monte Carlo

135 The performance of traditional stochastic random walk methods, such as Metropolis-  
 136 Hastings (Metropolis et al., 1953; Hastings, 1970), tends to scale poorly with increas-  
 137 ing dimension (Betancourt, 2017). One way to guarantee the efficacy of sampling is through  
 138 informed proposals, a strategy to ensure that the transitions largely follow the contours  
 139 of high probability mass (Neal, 1996, 2011; Betancourt, 2017). Informed algorithms, such  
 140 as Hamiltonian Monte Carlo (HMC) are designed to make use of the information out-  
 141 side of a simple target distribution evaluation at a given point (e.g., Khoshkholgh et al.,  
 142 2020; Zanella, 2020). HMC relies on the gradient information of the misfit in order to  
 143 guide the sampler towards the areas of high-probability mass. It can be regarded as a  
 144 hybrid approach encompassing the virtues of both gradient-based optimization and derivative-  
 145 free Markov chain Monte Carlo methods (Fichtner, Zunino, & Gebraad, 2018).

146 Hamiltonian Monte Carlo is particularly useful for multi-dimensional problems with  
 147 high quality data or weakly constrained priors, which, in traditional, derivative-free sam-  
 148 pling algorithms would result in a low acceptance rate and a slow convergence. Although  
 149 introduced in the 1980s (Duane et al., 1987), HMC has only recently gained popularity  
 150 in geophysics. Maiti and Tiwari (2009) implemented HMC-based neural networks to an-  
 151 alyze well log data, Muir and Tkalčić (2020) applied HMC for a lowermost mantle study,  
 152 Sen and Biswas (2017) and Biswas and Sen (2017) used HMC in 1-D and 2-D seismic  
 153 inversions, respectively, while Fichtner, Zunino, and Gebraad (2018) and Gebraad et al.  
 154 (2020) further proved the potential of HMC for nonlinear seismic tomography problems.  
 155 Very recently Aleardi et al. (2020) used HMC in the context of dispersion curves inver-  
 156 sion, while Koch et al. (2020) implemented adjoint HMC in the context of engineering.  
 157 A variant of HMC that tunes itself while sampling was presented by Fichtner et al. (2021).

158 The potential of HMC in earthquake source inversion was demonstrated by Fichtner  
 159 and Simutè (2018), where the HMC was adapted for efficient source studies in complex  
 160 media, with synthetic examples and a real-data illustration. In this study, we largely rely  
 161 on the methodology presented in Fichtner and Simutè (2018) and perform multiple source  
 162 inversions with an expanded and improved data set.

Green’s functions computed for laterally averaged structure are not adequate for tectonically complex areas, especially subduction zones, which require a proper incorporation of 3-D Earth structure (e.g., Engdahl et al., 1977; Igel et al., 2002). Simplified Earth models affect the estimation of the centroid location and time (e.g., Dziewoński & Woodhouse, 1983; Hjörleifsdóttir & Ekström, 2010; Ferreira & Woodhouse, 2006; Smith & Ekström, 1996; Thurber, 1983; Morales-Yáñez et al., 2020), the seismic moment (e.g., Patton & Randall, 2002), as well as the moment tensor itself (e.g., Woodhouse, 1983; Newrkla et al., 2019; Hejrani et al., 2017; Scognamiglio et al., 2016; Ferreira & Woodhouse, 2006), which often manifest as spurious non-double couple components (Zahradník et al., 2015). However, radially symmetric Earth models, which allow for a computationally efficient way to obtain Green’s functions, are still commonly used in source inversion studies on the grounds that a suitable data selection might isolate data pertaining principally to the source (e.g., Woodhouse, 1983; Mustač & Tkalčić, 2016; Ford et al., 2009a; Staehler & Sigloch, 2014).

Motivated by the effects that unaccounted Earth structure potentially has on earthquake source solutions, and endorsing the need for uncertainty information, we propose a stochastic earthquake source inversion, based on the Hamiltonian Monte Carlo sampling algorithm. We start by introducing a heterogeneous, viscoelastic and radially anisotropic Earth model of the crust and upper mantle beneath the Japanese islands region, which is constructed for this study (section 2). We then introduce the formulation and practical aspects of forward and inverse problems (sections 3 – 5). Finally, we present multi-period centroid moment tensor inversion results of earthquakes at the Izu-Bonin trench (section 6). Owing to the Bayesian framework, we retrieve the uncertainty information as well as the inter-parameter trade-offs. We discuss the implications as well as the limitations of the study in section 7 and draw the concluding remarks in section 8.

To reduce the effect of 3-D Earth structure on estimated source parameters, we construct a full-waveform inversion model for the Japanese islands region, building on the velocity model previously constructed by Simutè et al. (2016) on the basis of waveform data in the 20–80 s period range. The model is viscoelastic, radially anisotropic and 3-D heterogeneous. For forward and adjoint modeling, we employ the GPU-accelerated spectral-element wave equation solver SES3D (Fichtner et al., 2009b; Gokhberg & Fichtner, 2016). We use time-frequency phase misfits (Fichtner & Igel, 2008) to quantify differences between observed and synthetic waveforms within automatically selected measurement time windows where waveform similarity is sufficient to avoid cycle skips (Krischer et al., 2015). The final model is the result of an iterative conjugate-gradient minimization of the misfit, with gradients computed by adjoint techniques (Tarantola, 1988; Tromp et al., 2005; Fichtner et al., 2006). We invert for isotropic P velocity  $v_p$ , SV velocity  $v_{sv}$ , SH velocity  $v_{sh}$ , and density  $\rho$ . Furthermore, we implement viscoelastic attenuation by using the QL6 attenuation model of Durek and Ekström (1996), which is, however, kept constant throughout the inversion. Since the focus of this work is on source inversion, we refer to Simutè et al. (2016) for a more detailed and technical description of the well-established full-waveform inversion method.

208

209

210

211

212

213

Starting with the model presented in Simutè et al. (2016), we performed 14 additional iterations using waveform data with a slightly broadened period range of 15 – 80 s. First, we completed seven iterations for the larger model domain shown in Fig. 1, which we also used previously (Simutè et al., 2016). Subsequently, we performed the remaining seven iterations for a smaller domain and with additional regional data, as indicated in Fig. 1. This was intended to specifically improve that part of the model which we later use for the computation of Green’s functions, needed for the Bayesian source inversion.

214 With this concrete application in mind, we primarily focus on waveform fit, limiting the  
 215 presentation of the structural model to a short paragraph at the end of this section.

216 The overall waveform misfit decreased by 24 % after the first seven iterations in  
 217 the larger initial domain, and by another 21 % during the subsequent seven iterations  
 218 in the smaller domain. More details on the misfit evolution are shown in the supplement-  
 219 ary Fig. S1.

220 In Fig. 2, we present a small but representative collection of waveform comparisons  
 221 across the model domain for four  $M_w$  5.0 –  $M_w$  5.8 shallow- to intermediate-depth events,  
 222 situated 1) at the Izu-Bonin trench, 2) off Kuyshu, 3) in the Sea of Japan, and 4) off the  
 223 east coast of Honshu. Together with the selected stations they represent model parts which  
 224 are relatively well covered by the data. Still, the waveform fit is not uniform across the  
 225 model domain. Observed waveforms for some paths, such as between event 19 and station  
 226 BO.KSK, or event 30 and the stations in central Japan, are well explained in terms  
 227 of both phase and amplitude. Other paths, in contrast, are characterized by a good match  
 228 in phase but show discrepancies in amplitude; for example, the path between event 16  
 229 and station BO.ABU. The latter is a general feature observed across the majority of the  
 230 traces, suggesting that the source mechanism may need improvement.

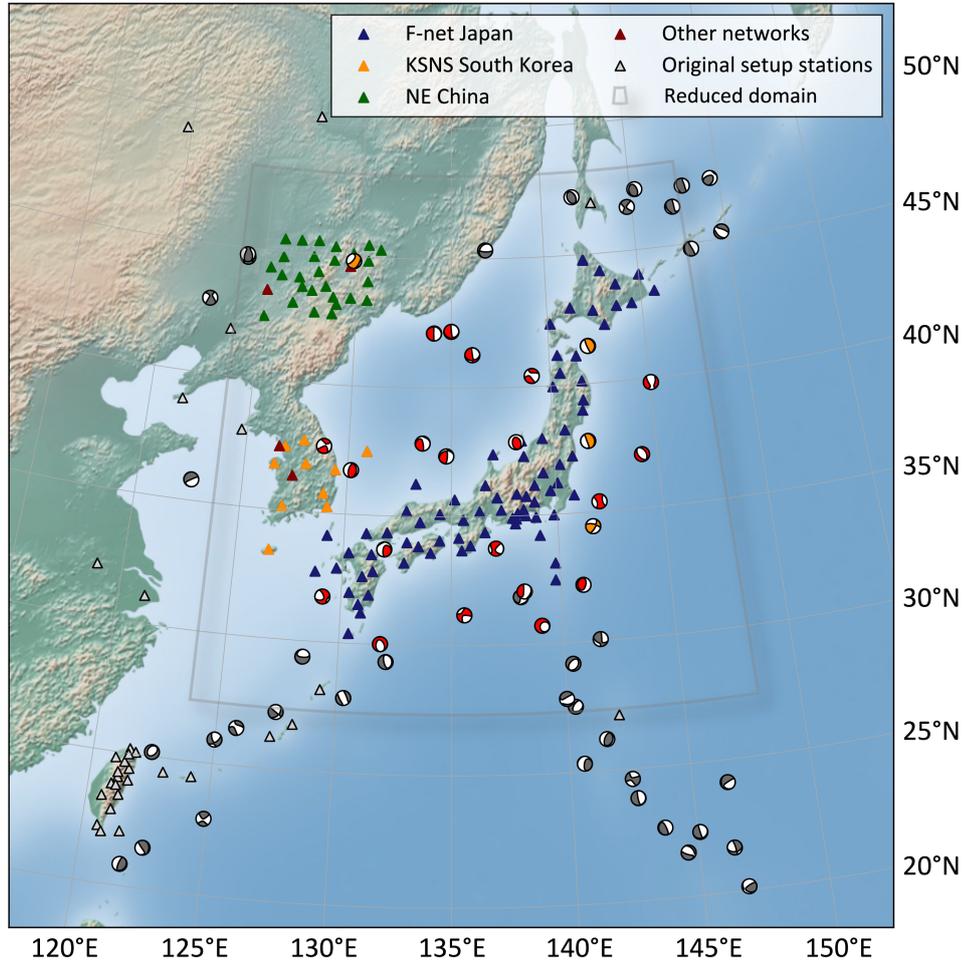

231 To assess the importance of using a 3-D model for source inversion in our study  
 232 region, we compare computed waveforms for our 3-D model (red solid waveforms in Fig.  
 233 2) and its laterally averaged 1-D version (red dashed waveforms in Fig. 2). The 3-D full-  
 234 waveform inversion model produces a substantially better waveform fit than the 1-D model,  
 235 for which time shifts can be on the order of tens of seconds. For the whole-Earth 1-D  
 236 model AK135 (Kennett et al., 1995) results are similar, thus corroborating that the lat-  
 237 eral heterogeneities in our velocity model are indeed required to fit waveform data at pe-  
 238 riods between 15 – 80 s, as studied here.

239 In Fig. 3 we compare the whole-seismogram waveform fit at short and long peri-  
 240 ods. The root-mean square error is computed as:

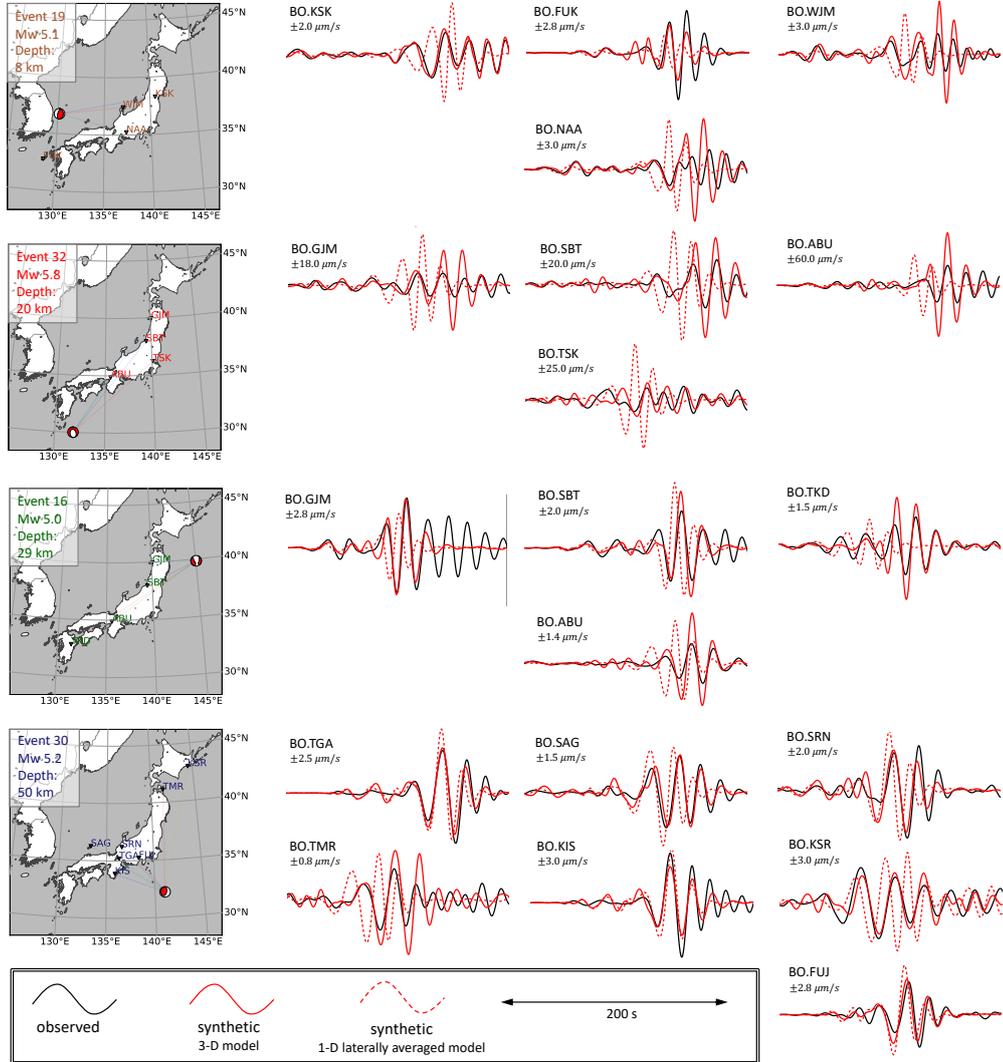

$$241 \quad \chi_i = \frac{\sqrt{\int_0^T [u_i^0(t) - u_i(t)]^2 dt}}{\sqrt{\int_0^T u_i^0(t)^2 dt}}, \quad (1)$$

242 where  $u_i^0(t)$  denotes the  $i$ -component of the observations,  $u_i(t)$  the  $i$ -component of  
 243 the synthetic seismograms, and  $T$  is the duration of the time series. Misfit at long-periods  
 244 (50–80 s) is low throughout the domain, with remaining discrepancies close to the ex-  
 245 pected noise level. Misfits at short-period (15–80 s), on the other hand, have more vari-  
 246 ability, largely correlating with the geological complexity along the source-receiver path.  
 247 The implications for the source inversion will be further discussed in section 5.4.

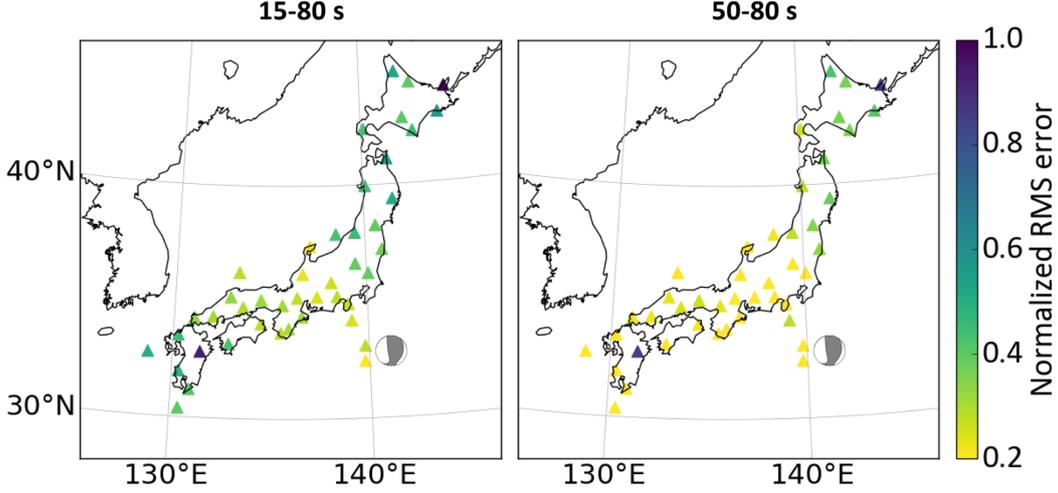

248 A collection of depth and cross-sectional slices through the tomographic model in  
 249 terms of deviation of the isotropic S velocity  $v_s$  from the lateral average  $\bar{v}_s$  is shown in  
 250 Fig. 4. We compute isotropic S velocity as  $v_s = \sqrt{\frac{2}{3}v_{sv}^2 + \frac{1}{3}v_{sh}^2}$  (e.g., Babuška & Cara,  
 251 1991; Panning & Romanowicz, 2006). The lateral average  $\bar{v}_s$  (Fig. S2), more depth slices  
 252 (Fig. S3), and depth profiles (Fig. S4) as well as anisotropy (Fig. S5), are presented as  
 253 supplementary information.

**Figure 1.** Source-receiver setups for tomographic inversions in the initial large domain and the smaller focused domain. Within the large domain, we used 58 earthquakes, depicted as red and grey focal mechanisms, and all the stations except for the NE China array, shown as triangles. The smaller domain comprises 20 events from the original setup shown in red and four new events in orange together with all seismic stations depicted in non-grey color.

**Figure 2.** Representative collection of observed waveforms (black), synthetic waveforms computed for the final 3-D model (solid red) and synthetic waveforms computed for the 1-D laterally averaged model (dashed red). The waveforms are filtered between 15 – 80 s. We show the vertical component of the waveforms for four events and selected stations, with the source-receiver configuration specified in a separate map for each earthquake. Event information, shown in the top left corner of each map, are NIED CMT solutions (Fukuyama et al., 2001).

**Figure 3.** Root-mean square (RMS) error between the vertical component of the observed data and the synthetic seismograms calculated for the Global Centroid-Moment-Tensor (GCMT) solution for the  $M_w$  5.2 event at 50 km depth depicted as a grey focal mechanism. The waveforms are filtered between 15–80 s (left) and 50–80 s (right). Misfits are normalized to the largest value of both scenarios. While longer-period data are well explained at the majority of the stations, more variation in misfit is present at shorter periods. Generally, stations in central Japan exhibit a very good fit, while those further away from the event, such as in Hokkaido or Kyushu, are characterized by slightly elevated misfits.

### 3 Forward problem

#### 3.1 Representation theorem

According to the representation theorem, the  $i$ -component of the displacement field  $\mathbf{u}$  in a point-source configuration can be expressed as a convolution of a time-dependent moment tensor  $M_{nq}(t)$  and Green’s strains  $G_{in,q}(\mathbf{x}, t; \boldsymbol{\xi}, \tau)$  (Aki & Richards, 2002):

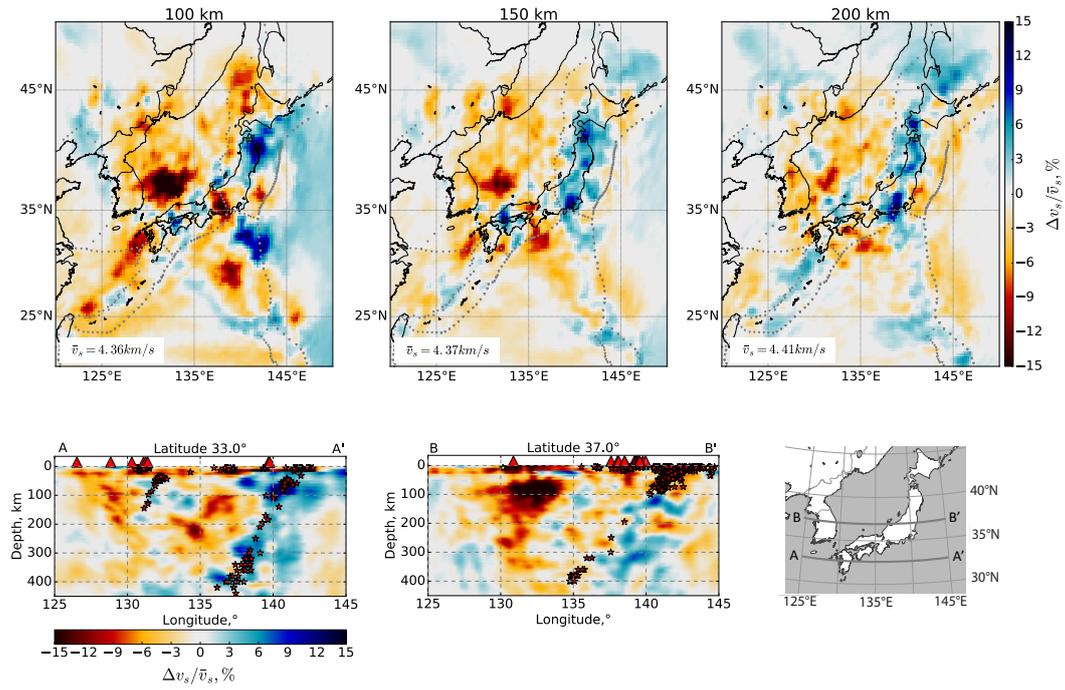

$$u_i(\mathbf{x}, t) = M_{nq}(t) * G_{in,q}(\mathbf{x}, t; \boldsymbol{\xi}, \tau), \quad (2)$$

where Green’s function  $G_{in}(\mathbf{x}, t; \boldsymbol{\xi}, \tau)$  is the  $i$ -component of the displacement field recorded at location  $\mathbf{x}$  and time  $t$  due to an impulse in  $n$ -direction at location  $\boldsymbol{\xi}$  and time  $\tau$ , and  $G_{in,q}(\mathbf{x}, t; \boldsymbol{\xi}, \tau)$  is a spatial gradient of Green’s function with respect to the  $q$ -coordinate of the source location, with  $,q$  denoting a derivative with respect to  $\xi_q$ . Einstein notation is implied.

In practice, it is often assumed that separate moment tensor components have the same time dependence, or the same source time function  $s(t)$  (e.g., Dziewoński et al., 1981; Ekström et al., 2012; Mustać & Tkalčić, 2016; Takemura et al., 2020; Zhu & Zhou, 2016), in which case a component of the displacement field can be expressed as:

$$u_i(\mathbf{x}, t) = M_{nq} s(t) * G_{in,q}(\mathbf{x}, t; \boldsymbol{\xi}, \tau). \quad (3)$$

The source duration of  $\sim M_w$  5 events, which we consider in this study, is usually a few seconds long (e.g., Vallée & Douet, 2016). Hence, we assume an instantaneous

**Figure 4.** Percentage perturbations of the isotropic S velocity, computed as  $\frac{v_s - \bar{v}_s}{\bar{v}_s} \times 100 \%$ , where  $\bar{v}_s$  is the lateral average of  $v_s$  for each depth. **Top panels:** horizontal slices, with dashed grey lines representing plate boundaries. **Bottom panel:** vertical cross-sections. Red and yellow stars represent earthquakes since 1997 and earthquakes used in this study, respectively, within  $1^\circ$  of the slice. Red triangles represent Holocene volcanoes (Siebert et al., 2010).

272 source time function, which is a sufficient approximation for the shortest periods we work  
 273 with, i.e., 15 s, which was also shown in the pilot study by Fichtner and Simutè (2018).  
 274 Assuming the same source time function for all events and all moment tensor compo-  
 275 nents, we can convolve  $s(t)$  with the Green’s strains at the time of computation, in which  
 276 case the displacement field becomes a linear combination of convolved Green’s strains  
 277 scaled by the moment tensor elements.

278 To ensure a rapid forward problem for probabilistic inference, we pre-compute and  
 279 store the Green’s strains in a database, taking advantage of spatial reciprocity. The mer-  
 280 its of reciprocity for the computations of Green’s functions have also been exploited in  
 281 previous studies (e.g., Eisner & Clayton, 2001; Zhao et al., 2006; Lee et al., 2011; Hejrani  
 282 et al., 2017; Okamoto et al., 2018; Takemura et al., 2020). The reciprocal formulation  
 283 of Eq. 3 can be found in Fichtner and Simutè (2018).

### 284 3.2 Database of Green’s strains

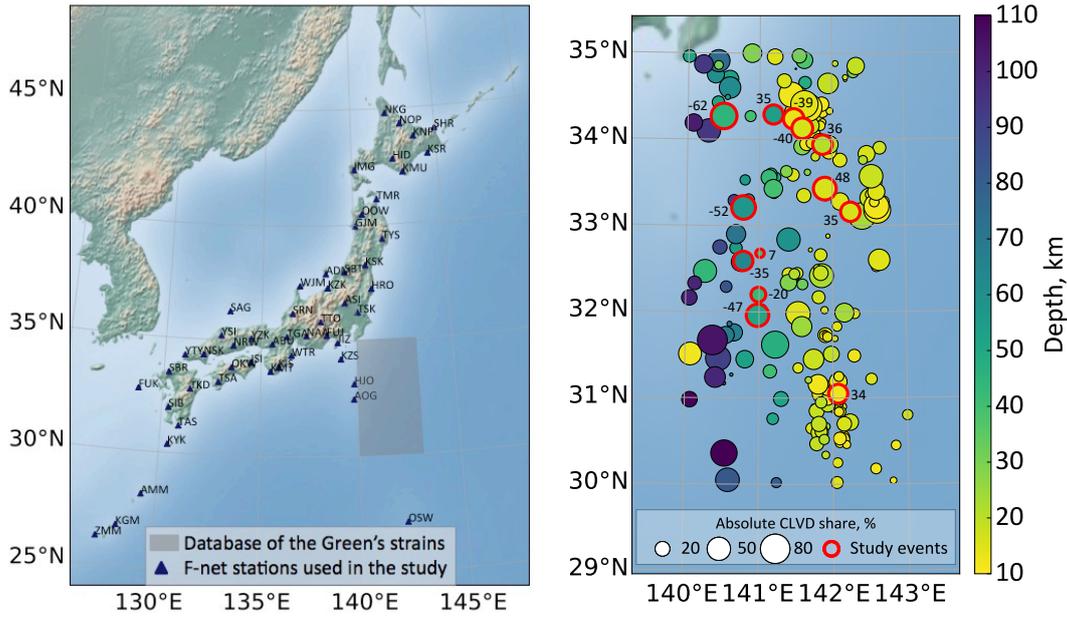

285 We compute Green’s strains numerically with the spectral-element solver SES3D  
 286 (Fichtner et al., 2009b; Gokhberg & Fichtner, 2016). Enabled by reciprocity, we treat  
 287 seismic stations as virtual sources and save the wavefield across the actual source area  
 288 of interest, i.e., the Izu-Bonin trench. To ensure a continuous representation of the wave-  
 289 field within the domain, we store the wavefield on Gauss-Lobatto-Legendre (GLL) points  
 290 of the fourth-order spectral-element method (SEM) grid and use the built-in polynomial  
 291 interpolation of SEM to extract the wavefield for any spatial coordinate. This contrasts  
 292 with the common practice of storing the Green’s functions on a pre-defined grid (e.g.,  
 293 Hejrani et al., 2017; Lee et al., 2011; Vackár et al., 2017; Takemura et al., 2020), where  
 294 one has to implement an interpolation routine or deal with a finite number of discrete  
 295 locations and possibly limit the spatial resolution of the earthquake location. Storing the  
 296 wavefield itself allows us to extract the strains for any potential source location and be  
 297 exempt from any additional parametrisation effects. We compute the database for over  
 298 50 selected F-net broadband stations (Fig. 5) uniformly distributed across the network  
 299 (National Research Institute for Earth Science and Disaster Resilience, 2021).

300 The source area of interest extends between  $140^{\circ}$ – $143^{\circ}$  E,  $30^{\circ}$ – $35^{\circ}$  N, and down  
 301 to 110 km depth. The downsampled wavefield with a time increment of 2 s takes 27 Gb  
 302 of space for a single virtual source, and the total storage requirements are 4.2 Tb. The  
 303 database is stored on Piz Daint supercomputer in the Swiss National Supercomputing  
 304 Centre, which we use to rapidly perform the inversions (Swiss National Supercomput-  
 305 ing Center, 2021).

## 306 4 Earthquake selection

### 307 4.1 Earthquakes in the area

308 The Izu-Bonin trench marks the boundary between the subducting Pacific plate  
 309 and the Philippine Sea plate. The trench is situated nearly linearly from north to south.  
 310 It is a steeply dipping subduction zone, with the angles of the Wadati-Benioff zone be-  
 311 tween  $50^{\circ}$  and  $70^{\circ}$  (Faccenna et al., 2018). Along the Izu-Bonin slab, seismicity extends  
 312 from the shallow surface down to the transition zone in the south and  $\sim 410$  km depth  
 313 in the north (Dziewoński et al., 1981; Ekström et al., 2012; Seno & Eguchi, 1983; Hayes  
 314 et al., 2012; Hayes, 2018). Following the global trend, the majority of events are located  
 315 in the upper  $\sim 60$  km (Kong et al., 2018; Hasegawa, 2011) (Fig. 5). At this depth, seis-  
 316 micity primarily occurs as a low-angle interplate thrust faulting, reflecting the relative  
 317 motion of the convergent plates (Hasegawa, 1990, 2011). Deeper down, earthquakes mostly  
 318 take place within the slab (Hasegawa, 1990, 2011). In the Izu-Bonin arc – an old plate  
 319 subduction zone – these intraslab events have the compressional axis predominantly ori-  
 320 ented in the dip direction (Hasegawa, 2011). In the overriding plate, the compression is

**Figure 5.** **Left:** setup of the stations and the source area used in the source inversion. Receiver-side Green's strains were computed from each seismic station, acting as a virtual source, and stored within the shaded source area. The strain database extends from the surface to 110 km depth. **Right:** distribution of earthquakes within the horizontal extent of the source area as given in the GCMT catalog between 1997 and 2020 (The Global CMT Project, 2021). The color of the circles corresponds to the depth of the earthquake, and the size to the absolute share of the CLVD component. Events used in this study are outlined in red. Depth scale saturates at a maximum depth.

321 accommodated by intraplate thrust fault or strike-slip fault earthquakes, with compres-  
 322 sional axis oriented in the direction of plate convergence (Hasegawa, 1990).

323 Given the complex nature of the subduction zone, earthquake mechanisms are di-  
 324 verse. Notably, there are numerous strongly non-double-couple (non-DC) events, with  
 325 compensated linear vector dipole (CLVD) component reaching up to 80 % of the total  
 326 moment (Fig. 5). There are physical explanations for CLVD mechanisms, such as simul-  
 327 taneous faulting of two non-parallel planes (Kuge & Kawakatsu, 1993), or complex fault-  
 328 ing with any deviation from unidirectionality in terms of a strike, dip or rake, with vol-  
 329 canic caldera collapse being a perfect example how many nearly simultaneous slips on  
 330 a curved fault result in an effective vertical-CLVD earthquake (Shuler et al., 2013; Net-  
 331 tles & Ekström, 1998; Fichtner & Tkalčić, 2010). However, very often an apparent CLVD  
 332 component is an artifact caused by a modeling error. Incorrect Earth structure, espe-  
 333 cially around the hypocenter of the earthquake, has a significant influence on moment  
 334 tensor estimation (Shuler et al., 2013; Burgos et al., 2016). For an intuitive understand-  
 335 ing, one can think in terms of a first-polarity inversion and a simple double-couple earth-  
 336 quake. The take-off angle depends on the velocity structure in which the earthquake is  
 337 embedded. When the take-off angle is incorrect, the inferred pressure (P) and tension  
 338 (T) axes, which correspond to the middle of dilatational and compressional quadrants,  
 339 respectively, are also incorrect (e.g., Newrkla et al., 2019). The inconsistencies can go  
 340 a long way, such that the mechanism can no longer be explained by a double-couple, and  
 341 the errors in modeling are then compensated by introducing a CLVD component. In-  
 342 ability to clearly distinguish between the physical versus apparent CLVD component in-  
 343 hibits our understanding of earthquake physics, while possibly incorrect focal mechanisms  
 344 hinders the accurate delineation of the local tectonic setting. Hence, by incorporating  
 345 complex Earth structure in our study we expect to see whether the CLVD component  
 346 is a physical feature of the earthquake or an artifact due to modeling errors.

## 347 4.2 Study events

348 We study events of moderate magnitudes, which fall within the area of our strain  
 349 database (Fig. 5) and have a significant CLVD component. Preference is given to more  
 350 recent earthquakes away from the database boundaries. We selected 13 events from the  
 351 Global Centroid-Moment-Tensor (GCMT) catalog (Dziewoński et al., 1981; Ekström et  
 352 al., 2012; The Global CMT Project, 2021). The earthquakes have moment magnitudes  
 353 between  $M_w$  4.8–5.3, are distributed within 13 km and 64 km depth with CLVD com-  
 354 ponent ranging between 7 % and 62 % (in absolute sense), with a median value of 36 %  
 355 (Fig. 5, 6, Table S1). The moment tensor decomposition is done after Vavryčuk (2015),  
 356 which has been adopted in previous studies (e.g., Vackár et al., 2017; Yu et al., 2019; Shang  
 357 & Tkalčić, 2020). We note that the deviatoric part of the moment tensor can be decom-  
 358 posed into a number of equivalent force combinations, and hence the choice is subjec-  
 359 tive (e.g., Jost & Herrmann, 1989).

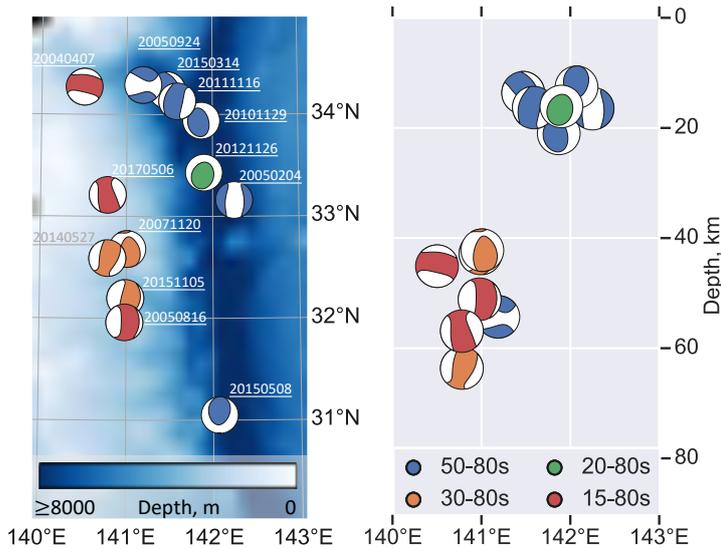

## 360 5 Inverse problem

### 361 5.1 Bayesian inference

362 We work in the Bayesian framework, where according to Bayes’ theorem (Bayes  
 363 & Price, 1763) the posterior probability density  $\pi(\mathbf{q}|\mathbf{d})$  of the model vector  $\mathbf{q}$  given the  
 364 data  $\mathbf{d}$  is:

$$365 \pi(\mathbf{q}|\mathbf{d}) = k\pi(\mathbf{d}|\mathbf{q})\pi(\mathbf{q}). \quad (4)$$

366 Bayes’ theorem provides a framework to enhance the existing knowledge, or the prior  
 367 probability density  $\pi(\mathbf{q})$ , with the new information from the data, that is, the likelihood  
 368  $\pi(\mathbf{d}|\mathbf{q})$  (Mosegaard & Tarantola, 2002; Mosegaard & Sambridge, 2002; Sambridge & Gal-

**Figure 6.** Distribution of earthquakes selected for this study. Earthquakes are plotted in terms of their focal mechanisms, with colors representing the shortest acceptable periods used for the inversion (see section 5.4 for more detail). **Left:** horizontal distribution of the events and their IDs plotted on the bathymetric map. **Right:** depth distribution of the study events. Deeper events can be modeled over a wider frequency range compared to the shallow ones.

369 lagher, 2011; Fichtner, 2021). The likelihood term contains information on the data fit,  
 370 i.e., how well the current model can explain the data. A constant  $k$  ensures the integral  
 371 of the posterior probability density over the model space is equal to 1 (e.g., Sambridge  
 372 & Mosegaard, 2002; Mustac̆ & Tkalčić, 2016; Staehler & Sigloch, 2014).

373 We express the likelihood  $\pi(\mathbf{d}|\mathbf{q})$  as the exponential function of the negative  $L_2$  mis-  
 374 fit between the synthetic and the observed waveforms,  $\mathbf{s}$  and  $\mathbf{d}$ , respectively:

$$375 \quad \pi(\mathbf{d}|\mathbf{q}) \propto \exp(-\chi), \quad (5)$$

$$376 \quad \chi = \frac{1}{2}(\mathbf{s}(\mathbf{q}) - \mathbf{d})^T \mathbf{C}_D^{-1}(\mathbf{s}(\mathbf{q}) - \mathbf{d}), \quad (6)$$

377 where  $\mathbf{C}_D$  denotes the data covariance matrix.

## 378 5.2 Hamiltonian Monte Carlo

379 We pursue Bayesian inversion with the Hamiltonian Monte Carlo method. Orig-  
 380 inally introduced as *hybrid* Monte Carlo (Duane et al., 1987), the method derives from  
 381 molecular dynamics simulation, used to study the properties of many-body systems by  
 382 solving Newton’s equations of motion (e.g. Xu & Li, 2008; Alder & Wainwright, 1959;  
 383 Neal, 1993). In short, HMC can be regarded as an efficient proposal mechanism, which  
 384 relies on exploiting gradient information of the model parameters. The main idea of the  
 385 algorithm is to follow a contour of high-probability, which is achieved by balancing the  
 386 gradient, or the *force*, by an artificially introduced *momentum*.

387 To set the stage for HMC, we first expand our model parameter space, described  
 388 by the  $N_q$ -dimensional position vector  $\mathbf{q}$ , with auxiliary momentum parameters  $\mathbf{p}$ . For

389 physical intuition of the sampling process one could imagine a mechanical particle in phase  
 390 space. To propose a new sample, a particle is set into motion by randomly assigning mo-  
 391 mentum to each model parameter. The particle then travels along the trajectory for some  
 392 artificial time  $\tau$ . The end of the trajectory serves as a new proposal. By marginalizing  
 393 over the artificially introduced momentum, we can retain only the position variables, i.e.,  
 394 the physical part of the phase space, which we are actually interested in. Mathemati-  
 395 cally, the trajectory is governed by Hamiltonian dynamics:

$$396 \quad \frac{dq_i}{d\tau} = \frac{\partial K}{\partial p_i}, \quad \frac{dp_i}{d\tau} = -\frac{\partial U}{\partial q_i}, \quad i = 1, \dots, N_q, \quad (7)$$

397 where potential energy  $U$  is expressed as:

$$398 \quad U(\mathbf{q}) = -\ln \pi(\mathbf{q}|\mathbf{d}), \quad (8)$$

399 and kinetic energy must be defined by the implementation. In this study we use:

$$400 \quad K(\mathbf{p}) = \frac{1}{2} \mathbf{p}^T \mathbf{M}^{-1} \mathbf{p}, \quad (9)$$

401 where the positive-definite mass matrix  $\mathbf{M}$  is a tuning parameter, which, generally speak-  
 402 ing, acts as a scaling parameter to ensure that momentum is tailored to the sensitivity  
 403 of each model parameter. This in turn allows us to explore the space equally well for each  
 404 parameter. The solution of Hamilton's equations throughout the artificial time  $\tau$  rep-  
 405 represents the evolution of the model in phase space. The discretization of artificial time  
 406 and the total length of the trajectory,  $L$ , are the tuning parameters of HMC. The dy-  
 407 namics conserves the total energy  $H$  throughout the Hamiltonian trajectory:

$$408 \quad H(\mathbf{q}, \mathbf{p}) = U(\mathbf{q}) + K(\mathbf{p}). \quad (10)$$

409 To solve the differential equations (Eq. 7), we numerically integrate using a leapfrog  
 410 algorithm, which preserves the volumes of regions of phase space, meaning, that by mov-  
 411 ing from one region in phase space to another, the points retain the same volume and  
 412 reversability in time, two properties important for HMC (Neal, 1993, 2011). The total  
 413 energy, on the other hand, is not conserved by the leapfrog algorithm, and this affects  
 414 the acceptance rate of the proposed samples.

415 The algorithm is performed in steps, starting with some model  $\mathbf{q}$ :

- 416 1. Draw momentum values from the multivariate normal distribution  $\exp(-\frac{1}{2} \mathbf{p}^T \mathbf{M}^{-1} \mathbf{p})$ .
- 417 2. With  $\mathbf{q}$  and  $\mathbf{p}$  specified, solve Hamilton's equations (Eq. 7).
- 418 3. The end of the trajectory marks a newly proposed sample in terms of  $\mathbf{q}(L)$  and
- 419  $\mathbf{p}(L)$ . After evaluating the total energy of the new sample,  $H$ , the model is ac-
- 420 cepted with probability:

$$421 \quad \Pi_{accept} = \min \left[ 1, \frac{\exp[-H(\mathbf{p}(L), \mathbf{q}(L))]}{\exp[-H(\mathbf{p}, \mathbf{q})]} \right]. \quad (11)$$

- 422 4. Repeat the procedure from step (1). If the sample is accepted, use  $\mathbf{q}(L)$  as a new
- 423 starting point, otherwise, return to the beginning of the trajectory and reuse model
- 424  $\mathbf{q}$ .

425 For technical aspects and choice of tuning parameters of HMC we refer the reader  
 426 to Fichtner and Simuté (2018).

427

### 5.3 Inversion parameters

428

429

430

431

432

433

434

435

436

437

In this study we seek a centroid-moment tensor solution, which means we simultaneously infer a centroid location, centroid time and a moment tensor of an earthquake (Dziewoński & Woodhouse, 1983). We invert for a full moment tensor, i.e., six independent components  $M_{ij}$ . By not imposing any constraints on the faulting mechanism, we allow the mechanism to be determined freely by the data. If a parameter or a combination of parameters cannot be constrained by the data, i.e., it lies in the null space of the model space, this shall be seen in the uncertainties provided by the probabilistic inference. For the comparison purposes, we also run a separate inversion for each case imposing a zero-trace constraint on the moment tensor, which denotes a source with no volumetric component.

438

439

440

441

442

443

Working with the moment tensor components  $M_{ij}$  is a subjective choice, and various alternatives exist (Tape & Tape, 2013). An advantage of the probabilistic approach used in this work is that the subjective component is explicit, and that it can be modified via a simple re-parameterisation of the involved probability densities. Hence, if needed, results can easily be presented in any different parameterisation, without suffering from subjective regularisation bias.

444

445

446

447

448

449

450

451

452

453

454

455

456

457

458

459

For the misfit computation we select measurement windows from the full waveforms manually and prescribe weights in order to preserve information carried by the body waves, which would otherwise be suppressed by the larger-amplitude surface waves. Assuming uncorrelated Gaussian data noise, our data covariance matrix  $\mathbf{C}_D$  is a diagonal matrix, entries of which we conservatively estimate from the pre-signal noise. We express prior probability density on model parameters as Gaussian distributions with standard deviations around ten times larger than the parameter mean for the moment tensor elements ( $1 \times 10^{17}$  N m), and  $2^\circ$ , 20 km, and 2 s for horizontal location, depth, and centroid time, respectively. The priors are intentionally made very wide in order to put emphasis on the constraints provided by the data and to not bias the inference too much by the prior. As a prior mean we commonly use the solution provided by the GCMT (Dziewoński et al., 1981; Ekström et al., 2012). However, for some events (IDs 20050816, 20040407) we update the location first by running a preliminary inversion with a reduced number of samples, and then use the maximum-likelihood model from this inversion as a prior mean for the main inversion. We refer to the maximum-likelihood model, as the one having the minimum potential energy  $U$  (Eq. 8).

460

### 5.4 Multi-period band inversion

461

462

463

464

465

466

467

468

Seismic waves traveling through complex geology for many wavelengths accumulate complicated path effects, such as frequency-dependent scattering or focussing in the presence of seismic velocity heterogeneities, which become more pronounced at shorter periods (e.g. Igel & Gudmundsson, 1997; Igel et al., 2002; Ferreira & Woodhouse, 2007). While our tomographic model can explain the majority of the waveforms in the 15–80 s period band, some complexities remain unaccounted for. This is primarily because strongly heterogeneous geology (e.g., accretionary prisms in the subduction zones) cannot be fully resolved by our limited data, especially due to non-uniform source-receiver distribution.

469

470

471

472

473

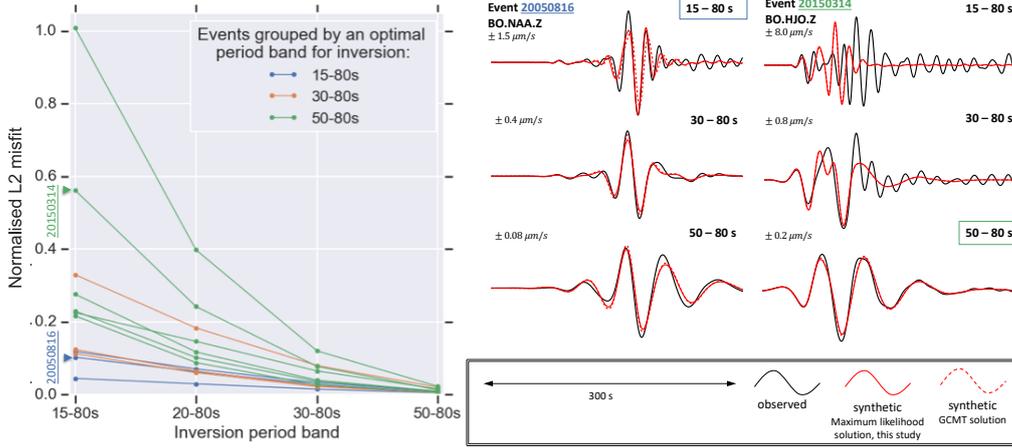

As expected, our model explains longer-period data better (Fig. 3), but omitting shorter periods reduces the information content carried by the waveforms. Hence, we are faced with a trade-off between a very good long-wavelength Earth model and the available short-period information, which is necessary to constrain a full moment tensor, including its volumetric component.

474

475

476

In our approach we perform multi-period band inversions, which means that we invert the same event using different period data, i.e., 15–80 s, 20–80 s, 30–80 s, and 50–80 s. In the analysis we only consider those event – period-band configurations for which

**Figure 7.** **Left:**  $L_2$  misfit (Eq. 6) between the observed data and the synthetics for the maximum-likelihood model from the inversion at each of the four period bands. The misfits are computed for the vertical component and are normalized to the largest value for visualization. Misfits have a high variance at short periods, but converge to a similar value for long-period inversions, indicating that data are not equally well explained for events at short periods. **Right:** waveform fit for two selected earthquakes in different period bands. The acceptable inversion period band of event 20050816 (in blue) is 15–80 s. It has a good waveform fit at short, as well as long periods. The acceptable inversion period band of event 20150314 (in green) is 50–80 s. For all events, waveforms are better explained with increasing periods.

477 an adequate waveform fit between the synthetic seismograms for the maximum-likelihood  
 478 model and the observed data is achieved. The adequate waveform fit is guided by the  
 479  $L_2$  misfit between the observed data and the synthetic data (Eq. 6). The procedure is  
 480 not purely automatic and requires human interaction. The uncertainty of the  $L_2$  mis-  
 481 fit comes through its dependence on the estimated data noise and its assumed distribu-  
 482 tion. While this is fine in the inversion, where each event is considered separately, the  
 483 absolute comparison across events might be problematic, because it depends on the sub-  
 484 jectively assigned data error. That is why in addition to the  $L_2$  misfit, we also evaluate  
 485 traces visually.

486 At shorter periods, the misfits vary more significantly than at longer periods (Fig.  
 487 7). Waveforms of some events, which tend to be deeper, are explained better than those  
 488 from other events, which tend to be shallower. This is illustrated in the right column of  
 489 Fig. 7, where the waveforms for event 20150314 (GMCT depth 13.6 km) are not well ex-  
 490 plained at short periods, but the fit becomes adequate at long periods. Event 20050816  
 491 (GMCT depth 51.1 km), on the other hand, has an adequate waveform fit throughout  
 492 all the period bands. In our approach by varying the period, we seek an Earth model,  
 493 which could largely explain the observed data and could therefore, be used for the source  
 494 inversion.

495 In the following section we will investigate the results of three events inverted with  
 496 15–80 s, 30–80 s, and 50–80 s data and discuss the differences in solutions as seen by dif-  
 497 ferent period data. We will then group the events according to their shortest acceptable  
 498 inversion period and provide a general overview of events from each period band: three  
 499 aforementioned events inverted with 15–80 s period data, one event with 20–80 s,  
 500 three events with 30–80 s, and six events inverted with 50–80 s period data.

## 6 Inversion results

### 6.1 Multi-period band inversions of selected events

We present three events, each inverted with 15–80 s, 30–80 s, and 50–80 s period data, and discuss how data content affects the inversion results. The comparison is only possible for a small collection of events, for which the minimum misfit in all frequency bands is acceptable.

#### 6.1.1 Moment tensor solutions

We present ensembles of effective moment tensor solutions in Fig. 8. While the inversion results from 30–80 s and 50–80 s period data are similar to each other, the short-period inversion (15–80 s) constrains a more distinctive source mechanism. Results from the short-period inversion reveal a significantly larger DC component compared to the longer periods. Our 3-D Earth model enables us to use short-period data, which in turn minimizes, what appears to be, an apparent CLVD component. At long periods, despite the 3-D Earth model, the inherent trade-offs in the source parameters still persist, and an increase in DC component is smaller (Dufumier & Rivera, 1997; Fitch et al., 1981).

We note that using a 3-D Earth model and fixing the isotropic component to zero allows for a greater DC component compared to the GCMT solution across all period band inversions, with the largest DC share typically reached at the shortest periods. Double-couple components in constrained inversions tends to be higher than in the corresponding unconstrained inversions. This may indicate that the DC component is overestimated when the source parameters are inferred assuming no volumetric component, as is done in the majority of global earthquake catalogs (e.g., Clinton et al., 2006; Hutton et al., 2000; Dziewoński et al., 1981; Ekström et al., 2012; Kubo et al., 2002).

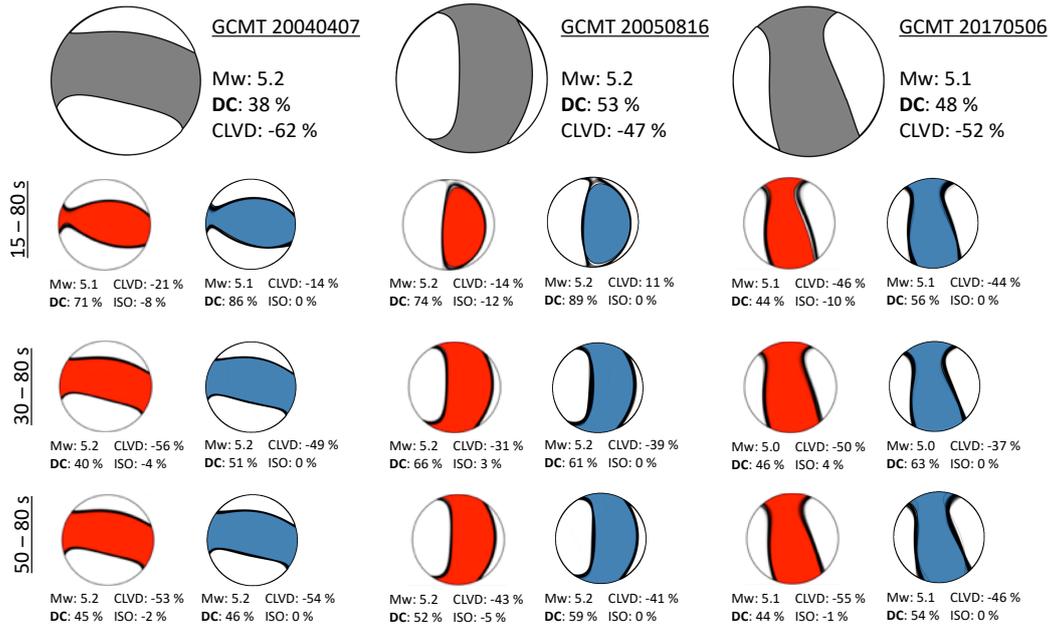

#### 6.1.2 Event locations

The ensembles of depth and horizontal location are presented in Fig. 9. There is variability of centroid locations across different period bands. Similarly to the moment tensor solutions, the centroid locations from the short-period data inversions deviate more significantly from the longer-period ones as well as from the GCMT solution. We note that event relocations are accompanied by a change in the moment tensor.

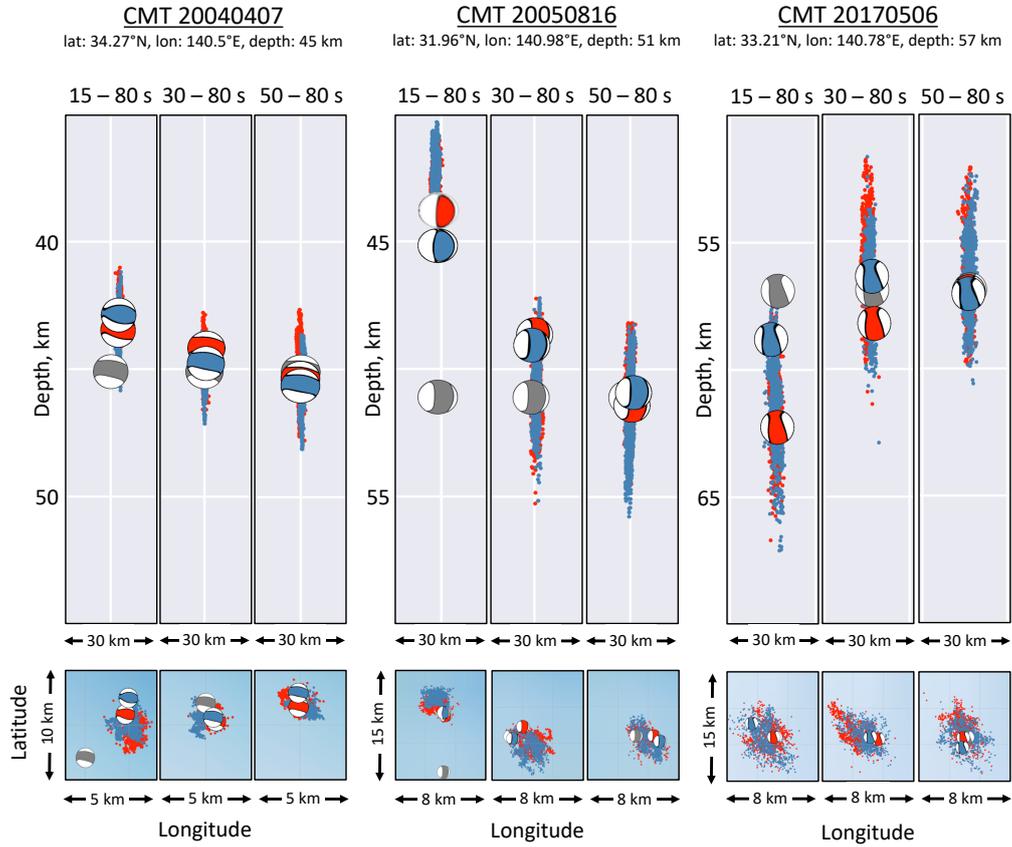

The most significant difference between the short- and the long-period depth solutions is seen for event 20050816. Long-period data prefer locations near the GCMT solution, while the location mean from the short period inversion (15–80 s) is around 9 km shallower and around 10 km northward than the corresponding mean from 50–80 s data inversion.

#### 6.1.3 Posterior probability densities

Generally, shorter-period data put tighter constraints on the source parameters compared to the longer-period data. This is reflected in the variances of individual model parameters for 15–80 s and 50–80 s period data inversions (Fig. 10). The largest differences are for the diagonal elements ( $M_{xx}$ ,  $M_{yy}$ ,  $M_{zz}$ ) of the moment tensor. In this particular example, location parameters have similar constraints from short- and long-period data inversions. An analogous comparison for another event is shown in Fig. S8. To demonstrate the inter-parameter trade-offs, we plot 2-D probability density marginals between the depth and all the other model parameters for 15–80 s and 50–80 s period inversions (Fig. 11). When shorter-period data are used, the posterior probability density distributions are more complicated (e.g., depth versus  $M_{yz}$ ,  $M_{xx}$ ) and appear multimodal. Because the multi-parameter distributions are not exactly Gaussian, maximum-likelihood

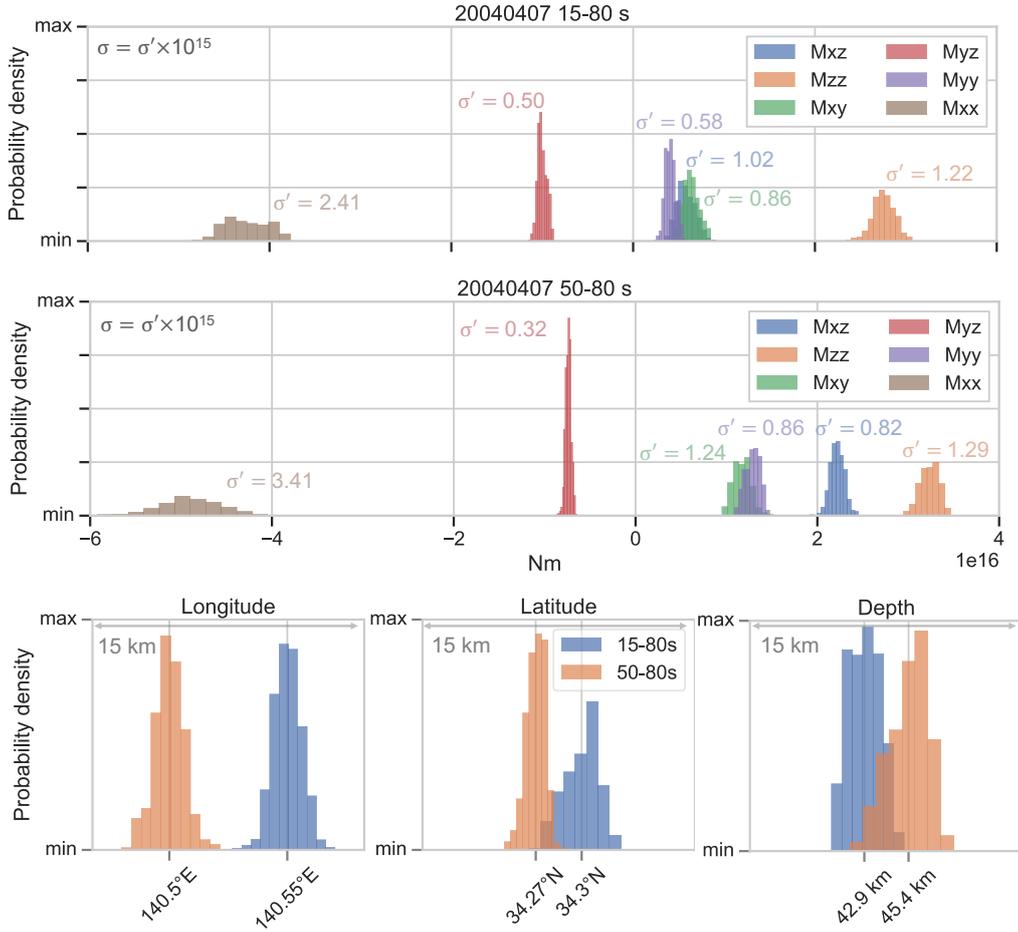

**Figure 8.** Ensembles of the focal mechanisms for three events inverted with 15–80 s, 30–80 s, and 50–80 s period data. Gray lines within the beachballs represent every 100th accepted model and the colored mechanisms correspond to the maximum-likelihood model. Red beachballs represent unconstrained inversions, and the blue ones inversions where the isotropic component is fixed to zero. Gray beachballs at the top represent the GCMT solution. The double-couple component of the constrained inversion exceeds that of the GCMT for all events in all period bands. Generally, the DC component reaches the highest value for the shortest-period data inversion and decreases with increasing period band.

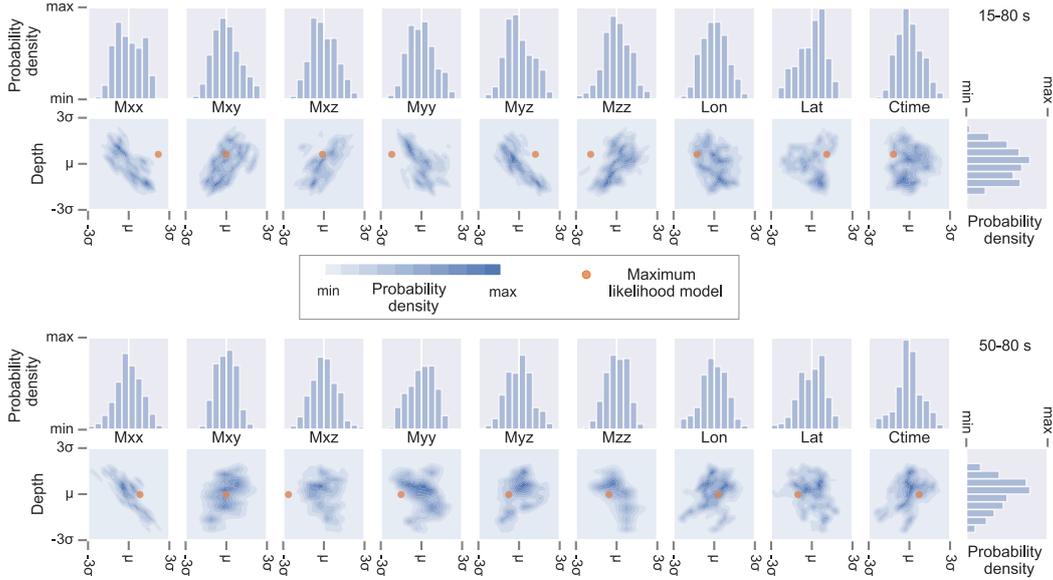

**Figure 9.** Ensembles of the location for three study events inverted with data of three different period bands, 15–80 s, 30–80 s, and 50–80 s. Red and blue dots represent every 100th accepted model from the unconstrained and constrained inversions, respectively. The maximum-likelihood model from each inversion is represented as a beachball following the same color code. Gray beachballs correspond to the GCMT solution. The model space around the GCMT location of event 20050816 has been explored at short-periods during the preliminary inversion, which was performed before the main one in order to update the event location used as a prior mean (Fig. S6).

547 models do not correspond to the mean values and might lie outside of the main prob-  
 548 ability density volumes (Fig. 11).

549 Depth trades off with the majority of the moment tensor components. For most  
 550 of the parameters the correlations are consistent for short- and long-period data inver-  
 551 sions (e.g., depth versus  $M_{xx}$ ,  $M_{yy}$ ). However, a positive trade-off between depth and  
 552  $M_{zz}$  at short periods becomes a negative one at long periods. When compared across  
 553 different events, we see that the trade-offs are not consistent, suggesting that it might  
 554 be the earthquake mechanism or location responsible for such a variability. For event 20050816,  
 555 for example, we see notorious trade-offs between depth and  $M_{yz}$  and  $M_{zz}$  at long peri-  
 556 ods, which are successfully reduced when the inversion is performed with shorter-period  
 557 data (Fig. 12). More parameters for event 20050816 are shown in Fig. S9.

**Figure 10.** Comparison of marginal probability densities inferred with 15–80 s and 50–80 s data for event 20040407. Marginal probability densities for moment tensor elements with standard deviation values are shown in the top two graphs, both of which are plotted on the same scale. Marginal probability densities for location parameters are shown below. Generally, shorter-period inversion constrains the inversion parameters better. This is especially true for the diagonal elements ( $M_{xx}$ ,  $M_{yy}$ ,  $M_{zz}$ ) of the moment tensor.

**Figure 11.** Comparison of selected trade-offs and marginal probability density functions for 15–80 s (top) and 50–80 s (bottom) period data inversion of event 20040407. The limits for each parameter depend on the corresponding standard deviations, and are set from  $\mu - 3\sigma$  to  $\mu + 3\sigma$ , where  $\mu$  is the mean and  $\sigma$  is the standard deviation of the distributions. When shorter-period data are used, the posteriors are more complicated (e.g.,  $M_{yz}$ ,  $M_{xx}$ ) and sometimes have several maxima. Because the multi-parameter distributions are not exactly Gaussian, maximum-likelihood models do not correspond to the mean values and for some parameters lie outside of the main probability densities. Depth trades off with the majority of the moment tensor components. For most of the parameters the trade-offs remain consistent for short- and long-period data inversions, however it is not always true (e.g.,  $M_{yz}$  and  $M_{zz}$ ). Although for this particular event, trade-offs seem to be stronger when short-period data are used, it is not a general feature across other events.

558

## 6.2 Waveform fit

559

560

561

562

563

564

565

566

567

568

In Fig. 13, we present the waveform fit for two events inferred with 15–80 s period data. Compared to the GCMT solution, the fit improves by 4 % for event 20050816 and 7 % for event 20040407 for the unconstrained inversion. The maximum-likelihood solution from the constrained inversion usually gives slightly worse fit compared to the unconstrained one, the difference is 1 % for the event 20040407 presented in the lower panel of Fig. 13. Although the numeric waveform fit improvement is relatively small, its effect on the source mechanism is significant. An improvement of 4 % for event 20050816 means 21 % increase in DC component (Fig. 8) and a depth relocation of 7 km (Fig. 9). Hence, large variations in source parameters are hidden in the subtle waveform differences, which are possible to extract only by virtue of a good Earth model.

569

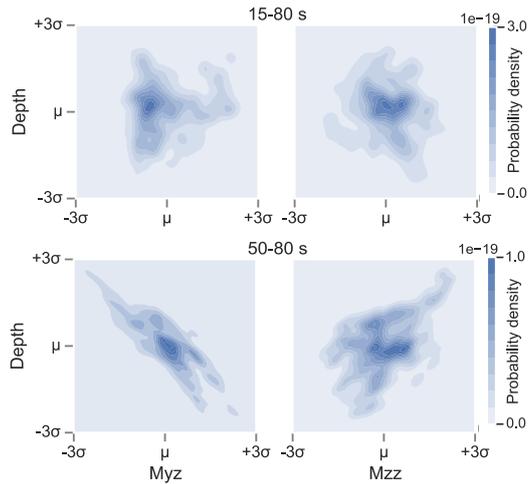

## 6.3 Statistical analysis

570

571

572

Here we present all events inverted in their shortest acceptable period band (see section section 5.4) and discuss those features of the results, which manifest across all the inversions.

**Figure 12.** Comparison of selected trade-offs for 15–80 s (top) and 50–80 s (bottom) period data inversions of event 20050816. The limits for each parameter depend on the corresponding standard deviations and are set from  $\mu - 3\sigma$  to  $\mu + 3\sigma$ , where  $\mu$  is the mean and  $\sigma$  is the standard deviation of the Gaussian-approximated distributions. For this event, the notorious trade-offs between depth and  $M_{yz}$  and  $M_{zz}$  are reduced when the inversion is performed with shorter-period data.

573

### 6.3.1 Moment tensor type across different inversions

574

575

576

577

578

579

The inversion results from short-period data (15–80 and 20–80 s) show a significant increase in the DC component, when compared to the GCMT solutions (Fig. 14). In the case of unconstrained inversion, DC component increases by up to 33 % (event 20040407), with isotropic component not exceeding 12 %. The source mechanisms from the constrained inversion have even stronger DC component. It increases by up to 48 %, and reaches more than 85 % for all but one earthquake.

580

581

582

583

584

585

586

587

The results obtained with longer-period data (30–80 s and 50–80 s) follow a different trend. Maximum-likelihood source mechanisms as well as locations stay similar to the GCMT values (Fig. 15). In the case of 30–80 s inversion, moment tensors from the unconstrained inversion show only a slight increase in DC component (2–3 %) with isotropic component not exceeding 2 %. Source solutions inferred with 50–80 s period data (Fig. 15) have negligible deviations from the GCMT solutions, both in terms of moment tensor and location. In other words, inversions at long periods have weaker constraints from the data and are dominated by the prior.

588

589

590

591

An overview of depth relocation across different inversions is presented in Fig. 16. Similar to the source mechanisms, the largest deviations in depth come from the shortest-period band inversions. Events inferred with 50–80 s period data maintain almost the same depth as given by the GCMT catalog.

592

### 6.3.2 Principal component analysis

593

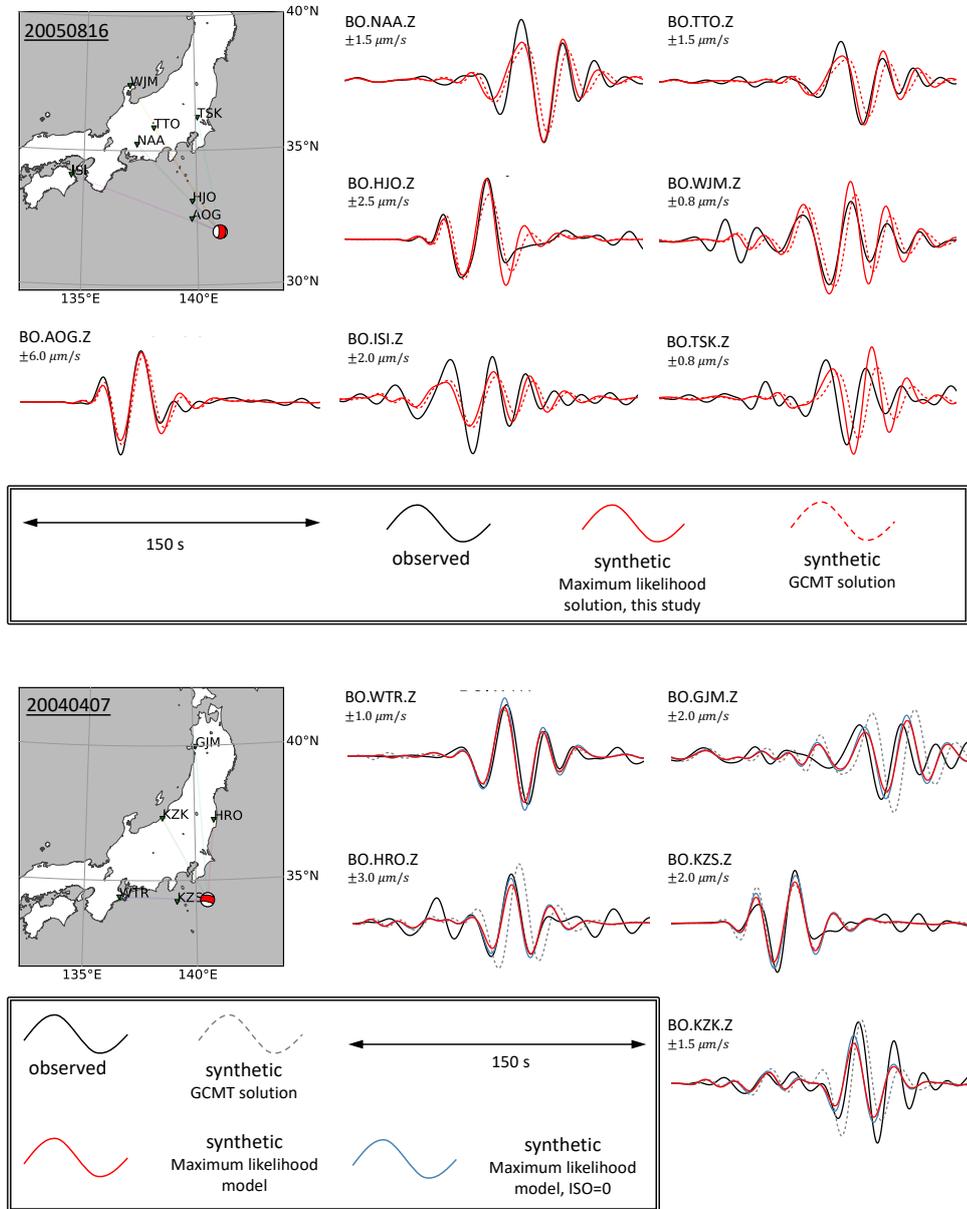

594

595

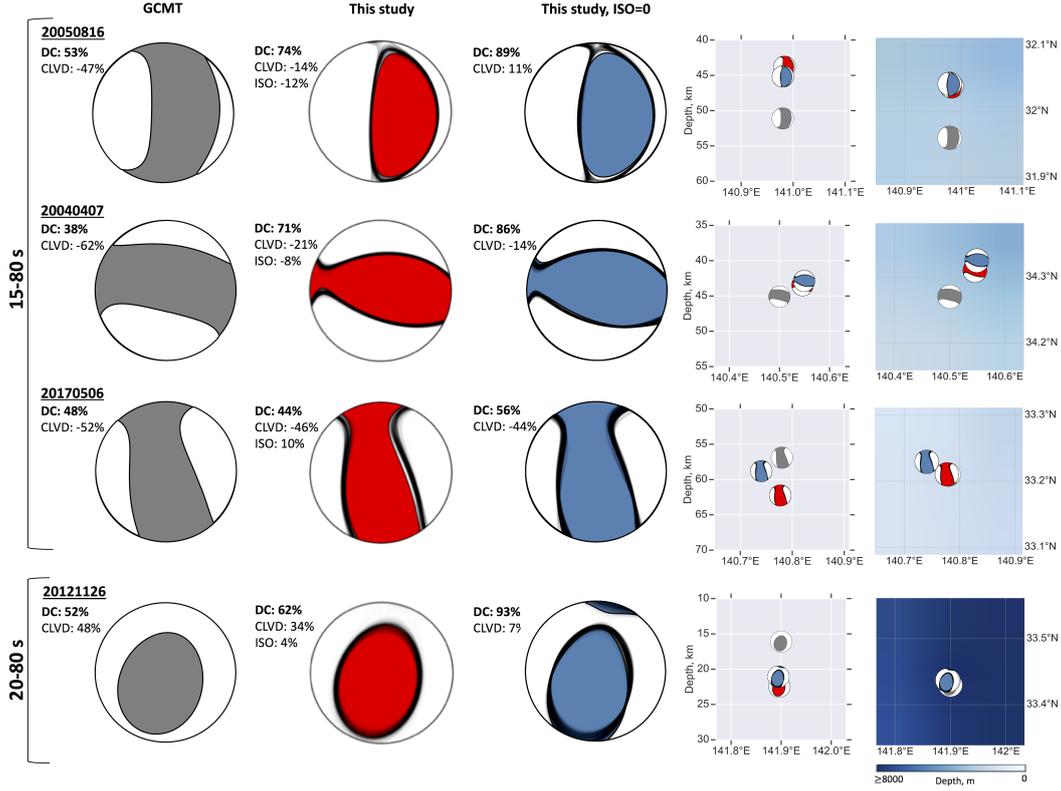

596

597

The value of probabilistic inversion lies in the statistical inferences which can be made from the ensembles of the accepted models. We can extract the moments, such as the mean value or the variance of the distribution, of the separate model parameters, and after marginalization easily visualize the 1-D probability density distributions (Fig. 10). To study inter-parameter trade-offs, it is common to plot 2-D marginal probability den-

**Figure 13.** **Top:** waveform fit between the observed data (black), synthetic data for the maximum-likelihood model of 15–80 s period unconstrained inversion (solid red) and synthetics for the GCMT solution (red dashed) for event 20050816. **Bottom:** waveform fit between the observed data (black), synthetic data for the maximum-likelihood model of 15–80 s period unconstrained inversion (solid red), synthetic data for the maximum-likelihood model from the constrained inversion (blue) and synthetics for the GCMT solution (gray dashed) for event 20040407.

**Figure 14.** Moment tensor ensembles inferred with 15–80 s (top three) and 20–80 s period data (bottom one). Gray beachballs correspond to the GCMT solution, red beachballs correspond to an unconstrained inversion, and blue ones correspond to the inversion, where we assume no volumetric component. Gray lines represent every 100th model of the ensemble, with the maximum-likelihood models colored. On the right, we show the maximum-likelihood locations, following the same color code. The horizontal relocation from the GCMT solution amounts to several kilometers.

598 sites (Fig. 11). However, anything higher than two dimensions becomes difficult to vi-  
 599 visualize and to study. In order to better understand the posterior distribution of the multi-  
 600 dimensional parameter space, we propose to perform a principal component analysis (PCA).

601 PCA works by introducing a new coordinate system of the model space, which em-  
 602 phasizes the variation in the distribution. Each new axis, called principal component (PC),  
 603 is a linear combination of the physical model parameters. Depending on the type of ob-  
 604 servations or model parameters, PCA can be performed either on the covariance or on  
 605 the correlation matrix.

606 The covariance matrix is defined as:

$$607 \quad \text{cov}(\mathbf{X}) = \mathcal{E}[(\mathbf{X} - \boldsymbol{\mu}\mathbf{1}_N^T)(\mathbf{X} - \boldsymbol{\mu}\mathbf{1}_N^T)^T] = \begin{pmatrix} \sigma_{11} & \sigma_{12} & \cdot & \sigma_{1K} \\ \sigma_{21} & \sigma_{22} & \cdot & \sigma_{2K} \\ \cdot & \cdot & \cdot & \cdot \\ \sigma_{K1} & \sigma_{K2} & \cdot & \sigma_{KK} \end{pmatrix}, \quad (12)$$

608 where  $\mathbf{X}$  is the ensemble of sampled model parameter vectors. It is a  $K \times N$  ma-  
 609 trix, where  $K$  is the number of parameters, and  $N$  is the number of samples. The model

610 mean vector  $\boldsymbol{\mu}$  is multiplied by an  $N \times 1$  vector of ones, and  $\mathcal{E}$  denotes the expected value  
 611 of the product in the square brackets. Because our model parameters are incommensu-  
 612 rable, i.e., they have diverse physical units, such as s or Nm, and variances with orders  
 613 of magnitude ranging from  $1 \times 10^{-4}$  to  $1 \times 10^{30}$ , we work with a correlation matrix (Chave,  
 614 2017). The correlation matrix is characterized by the normalized covariances, but nev-  
 615 ertheless, retains the inter-parameter trade-offs:

$$616 \quad \text{corr}(\mathbf{X}) = \begin{pmatrix} 1 & \rho_{12} & \cdot & \rho_{1K} \\ \rho_{21} & 1 & \cdot & \rho_{2K} \\ \cdot & \cdot & \cdot & \cdot \\ \rho_{K1} & \rho_{K2} & \cdot & 1 \end{pmatrix} \quad (13)$$

617 where  $\rho_{jk} = \sigma_{jk} / \sqrt{\sigma_{jj}\sigma_{kk}}$ .

618 The first principal component, or an eigenvector with the corresponding largest eigen-  
 619 value, is responsible for the largest variance of the distribution. In our case this corre-  
 620 sponds to the greatest uncertainty axis. The best-constrained direction of the multi-dimensional  
 621 distribution is represented by the smallest PC, indicating the narrowest extent of the dis-  
 622 tribution. The exact share of the explained variance is proportional to the size of the eigen-  
 623 value. If there are no dominant eigenvalues and all of them are of a comparable size, it  
 624 means that all the principal components, or the effective parameters, are resolved with  
 625 a similar (un)certainty. The correlation matrix is then close to being proportional to the  
 626 identity matrix, resembling a multi-dimensional sphere (Chave, 2017). In a dataset of  
 627 observations, if some threshold variance, typically set between 70 % and 90 %, can be  
 628 explained by much fewer PCs than a number of original parameters, one could retain only  
 629 the most important principal components, and benefit from the reduced dimensional-  
 630 ity of the problem (Chave, 2017).

631 We study principal components for the unconstrained inversion of each study event  
 632 at its corresponding shortest acceptable period band as presented in section 6.3.1. The  
 633 left column of Fig. 17 illustrates the cumulative explained variance by the principal com-  
 634 ponents for each event. We see that events inverted at longer periods (30–80 s, 50–80  
 635 s) reach the 70 % variance threshold with the first three and 90 % with the first five prin-  
 636 cipal components, while those inverted at shorter periods (15–80 s, 20–80 s) need four  
 637 for 70 % and seven for 90 % variance threshold. In other words, the eigenvalues from the  
 638 long-period inversions show larger variability than those from the shorter-period inver-  
 639 sion. From this we can deduce that the shape of multi-dimensional distribution for longer-  
 640 period inversions diverge from the sphere more than for the short-period inversions. This  
 641 means that for an event inverted at long periods, some axes (e.g., PC 0) are much more  
 642 difficult to constrain than others (e.g., PC 9), while at shorter periods, they can all be  
 643 constrained more equally.

644 In order to ascertain whether these certainty and uncertainty axes are similar across  
 645 all the inversions, we investigate similarity of the principal components among the dif-  
 646 ferent events by computing the dot product between PCs associated i) with uncertainty  
 647 (PC 0–PC 4) and ii) certainty (PC 5–PC 9) within the same period band inversions. Putting  
 648 a threshold of  $30^\circ$ , we find no consistency among the axes corresponding to either the  
 649 smallest or the largest eigenvalues. In other words, principal components are pointing  
 650 to different directions for each event and no linear combination of physical parameters  
 651 can be generalized to be the least- or the best-constrained direction in the model space.  
 652 This suggests that we cannot easily reduce the dimension of the problem by ignoring some  
 653 parameters, because the eigenvectors are different for each event. Because the data and  
 654 the azimuthal coverage are similar for all the study events, it is likely that the source mech-  
 655 anism or the centroid location are responsible for the fact, that each event is character-  
 656 ized by a very different set of principal components.

## 657 7 Discussion

### 658 7.1 Increase of double-couple component

659 Accounting for heterogeneous Earth structure enables us to use shorter-period data  
 660 (15–80 s, 20–80 s) in regional source inversion. This leads to a higher double-couple com-  
 661 ponent compared to GCMT solutions, and it suggests that at least part of the CLVD  
 662 component, given by the GCMT catalog, is likely to be an artefact caused by forward  
 663 modeling errors. A similar trend of increasing DC component when 3-D Earth structure  
 664 is taken into account has been shown by Hejrani et al. (2017) and X. Wang and Zhan  
 665 (2019) for earthquakes in the Papua New Guinea and Los Angeles regions, respectively.

### 666 7.2 Power of subtle waveform differences

667 Significant changes in source parameters, both in terms of moment tensor and lo-  
 668 cation, may occur despite relatively small waveform differences. In one of the examples  
 669 we showed that an overall waveform fit improvement of 4 % led to 21 % increase in DC  
 670 component together with a depth relocation of 7 km. This implies that some source pa-  
 671 rameters or combinations thereof are highly sensitive to subtle waveform differences and  
 672 Earth structure, and can therefore only be resolved with a reliable 3-D Earth model.

### 673 7.3 Effective source solutions

674 In this study we have presented effective, i.e., period-dependent, point-source so-  
 675 lutions, inferred with different-period data. In the following, we discuss means of how  
 676 varying frequency data can lead to effective source parameters.

#### 677 7.3.1 Source complexity

678 Spatial and temporal complexity of the source have been previously suggested to  
 679 explain the discrepancy between short- and long-period source mechanisms (e.g., Wal-  
 680 lace et al., 1982; Grandin et al., 2015; Frankel, 2013). For example, it has been argued  
 681 that asperities on the fault surface generate shorter-period seismic waves, while the over-  
 682 all faulting episode is represented by the long-period waveforms (Wallace et al., 1982).  
 683 However, a typical  $M_w$  5 event, such as those selected for our study, should not exceed  
 684 several seconds in half-duration and a few kilometers fault surface radius, which makes  
 685 it unlikely for 15 s period data to constrain a subfaulting episode, as the periods are much  
 686 longer than the expected duration of the earthquake (Ekström et al., 2012; Hanks, 1977;  
 687 Eshelby & Peierls, 1957).

#### 688 7.3.2 Near-source anisotropy

689 Another possibility, which could explain effective source solutions, is related to the  
 690 near-source heterogeneities and specifically, anisotropy. Anisotropy arises from different,  
 691 scale-dependent mechanisms (e.g., Backus, 1962; Kawakatsu et al., 2009; N. Wang et al.,  
 692 2013). Such a frequency-dependent nature of observed anisotropy has indeed been re-  
 693 ported beneath Japan (Wirth & Long, 2010) and other subduction zone regions (e.g.,  
 694 Fouch & Fischer, 1998; Greve & Savage, 2009). Anisotropy in the immediate vicinity of  
 695 the source can affect wave propagation in such a way that a purely isotropic event might  
 696 appear to have excited shear waves, while a shear earthquake might appear to have had  
 697 a non-DC component (e.g., Vavryčuk, 2004; Li et al., 2018). The effective source solu-  
 698 tions might arise from the fact that the fine-scale anisotropy is only captured by the shorter-  
 699 period waves, while longer-period waves sample an effective medium over larger scales.  
 700 Therefore, at short-period inversions (15–80 s), where the fine-scale anisotropy around  
 701 the source is accounted for, the apparent CLVD component decreases, while at long pe-  
 702 riods (50–80 s), it remains relatively high.

703 **7.3.3 Information content**

704 Long-period data may not contain enough information to properly constrain the  
 705 source parameters of relatively small-magnitude earthquakes. Firstly, data are more cor-  
 706 related at longer-periods and hence, carry less independent information. This results in  
 707 inherent trade-offs between moment tensor components, such as  $M_{zz}$  and  $(M_{xx}+M_{yy})$ ,  
 708 which trade off in the case of long-period surface wave inversion (Dufumier & Rivera,  
 709 1997; Fitch et al., 1981). Secondly, the amplitude spectrum of small-magnitude events  
 710 tends to decrease with increasing period (Aki, 1967), and hence, the signal-to-noise ra-  
 711 tio at long periods may therefore, be diminished.

712 Long-period data used in this study, i.e., body and surface waves in the 50–80 s pe-  
 713 riod band, are comparable to the data used to construct the GCMT catalog. The reported  
 714 minimum periods of body and surface waves, used to constrain the earthquakes chosen  
 715 for our study, are 40 s and 50 s, respectively (The Global CMT Project, 2021). Although  
 716 the azimuthal coverage in the GCMT inversion may be more complete than in our study,  
 717 due to the available teleseismic data, the lack of seismic receivers in the north-western  
 718 Pacific Ocean is evident (Ekström et al., 2012). Similarity between data periods could  
 719 potentially explain why our long-period source solutions are in a close agreement with  
 720 the GCMT predictions.

721 **7.4 Effect of the prior**

722 The source parameters constrained with long-period data are often very close to  
 723 the prior model, i.e., the GCMT solution, which we use for the majority of the inversions.  
 724 In the Bayesian framework, the fact that the posterior closely resembles the prior can  
 725 mean two things: either the likelihood is very similar to the prior and hence prefers the  
 726 same solution, or the data constraints are weak, and the posterior is dominated by the  
 727 prior probability density distribution.

728 Although stochastic algorithms are direct search methods, theoretically giving us  
 729 a chance to obtain probability density functions of a full model space, its practical im-  
 730 plementation might be very expensive, especially in a high-dimensional space. With the  
 731 aim to speed up the convergence and to alleviate computational costs, we introduced a  
 732 modified version of Hamiltonian Monte Carlo. If well tuned, HMC can be a very efficient  
 733 sampling algorithm for its gradient-based approach of proposing the samples. The deriva-  
 734 tive should in principle be computed at every point along the Hamiltonian trajectory.  
 735 However, this is expensive, and in our formulation we suggest to approximate the deriva-  
 736 tive around a prior mean in model space, instead (Fichtner & Simuté, 2018). The deriva-  
 737 tive is exact for the parameters linearly related to data (i.e., the moment tensor com-  
 738 ponents), but it is an approximation for nonlinear parameters (i.e., centroid). We note  
 739 that this approximation only concerns the samples drawn to be proposed, and not the  
 740 acceptance criterion, which should still ensure that even with this approximation, only  
 741 relevant models are accepted. Furthermore, if we let our sampler run for an infinite amount  
 742 of time, the way samples are proposed would not matter. However, during the finite run  
 743 time, the posterior might actually be biased towards the point in model space around  
 744 which the approximation is performed, which in our case is often prior mean.

745 **7.5 Data and modeling errors**

746 In this study we pragmatically treated observed data noise and forward modeling  
 747 errors. We estimated data noise from the pre-signal recordings, and assumed it to be nor-  
 748 mally distributed without spatial or temporal correlation. For this conceptual demon-  
 749 stration we also did not account for the forward modeling errors. Efforts to properly in-  
 750 corporate modeling errors and data noise covariances in stochastic inversions were made

by e.g., Staehler and Sigloch (2014, 2017); Vackár et al. (2017); Hallo and Gallovič (2016); Duputel et al. (2012).

## 7.6 Trade-offs between structure and source

Because of the trade-offs between Earth structure and earthquake source parameters, it is challenging to constrain them independently (e.g., Morales-Yáñez et al., 2020; Hjörleifsdóttir & Ekström, 2010; Hejrani et al., 2017). In this study, we proceed with a two-step approach: first we constrain the structure, then, with a suitable Earth model at hand, we aim to recover improved source parameters. In an idealized scenario, where the probability density distribution between the source and the structure parameters would be Gaussian, this procedure would look rather straightforward (Fig. 18). However, the real world presents many complications. Firstly, we do not have much constraints on the model space of the Earth structure except for the least-squares solution. Secondly, such a unimodal distribution might be an oversimplification. Lastly, the probability density distribution is likely to be frequency-dependent, with increasing complexity at increasing frequencies. Therefore, locating a global minimum in the source – structure space might actually be a very difficult task, especially at shorter periods.

## 8 Conclusions

We presented results of a probabilistic seismic source inversion for 13 small-to-moderate magnitude offshore earthquakes at the Izu-Bonin trench. The inversions were conducted using fully heterogeneous, radially anisotropic Green’s functions and the Hamiltonian Monte Carlo sampling algorithm. We simultaneously inferred centroid location, centroid time and six independent moment tensor components, and ran a separate inversion constraining the volumetric component to zero for comparison purposes. With the goal to use a sufficiently good Earth model, we varied the minimum inversion period and limited ourselves to those period bands, for which the data fit between the observed data and the maximum-likelihood solution was sufficiently good.

Accounting for 3-D Earth structure at short periods (15–80 s, 20–80 s) generally leads to an increase in DC component compared to the GCMT solution (Fig. 14). This suggests that at least some part of the non-DC component in the GCMT catalog might be apparent – resulting from unmodeled Earth structure. Events inverted at longer periods (e.g., 50–80 s) (Fig. 15), do not show a significant change in mechanism or centroid location and stay close to the GCMT predictions. We have presented several possible mechanisms to explain the effective solutions, the most likely being near-source propagation effects, which cannot be resolved by long-period data, or weakening data constraints with increasing periods.

Constraining isotropic component to zero is a common practice in order to stabilize the inversion and to prevent unexplained waveform differences from mapping into the additional parameter. Here, we observe that owing to the 3-D Earth model, isotropic component remains weak even when unconstrained.

The diagonal components of the moment tensor, which are responsible for the volumetric change, are significantly less constrained, compared to the off-diagonal ones (Figs. 10, S8). From the events which could be inverted in all period bands, we also see that shorter-period data constrain all the source parameters better than the long-period data (Figs. 10, S8). Posterior probability density distributions of shorter-period data inversions appear multimodal and are more complicated than those of long-period. This illustrates non-uniqueness of short-period source inversions and highlights the need for stochastic approaches.

798 We note that finding a solution, which has a significantly better waveform fit than  
 799 that provided by the GCMT catalog, is a challenging task. In our examples, the wave-  
 800 form fit only improves by several percent (Fig. 13). However, a small change in the wave-  
 801 forms brings about a significant change in the source solution. In other words, large vari-  
 802 ations in source parameters are hidden in the subtle waveform differences, which are pos-  
 803 sible to extract only by virtue of a good Earth model.

804 To aid the study of the multi-dimensional posterior, we perform principal compo-  
 805 nent analysis. We include all the study events at their shortest acceptable inversion pe-  
 806 riod band, with the aim to retrieve the best- or the least-constrained direction in model  
 807 space. By comparing the principal components (eigenvectors) corresponding to either  
 808 the smallest or the largest eigenvalues, we find no consistency among different events from  
 809 the same period-band inversion group. Each event is characterized by a very different  
 810 set of principal components, and no linear combination of physical parameters stands  
 811 out as the least- or the best-constrained direction in model space.

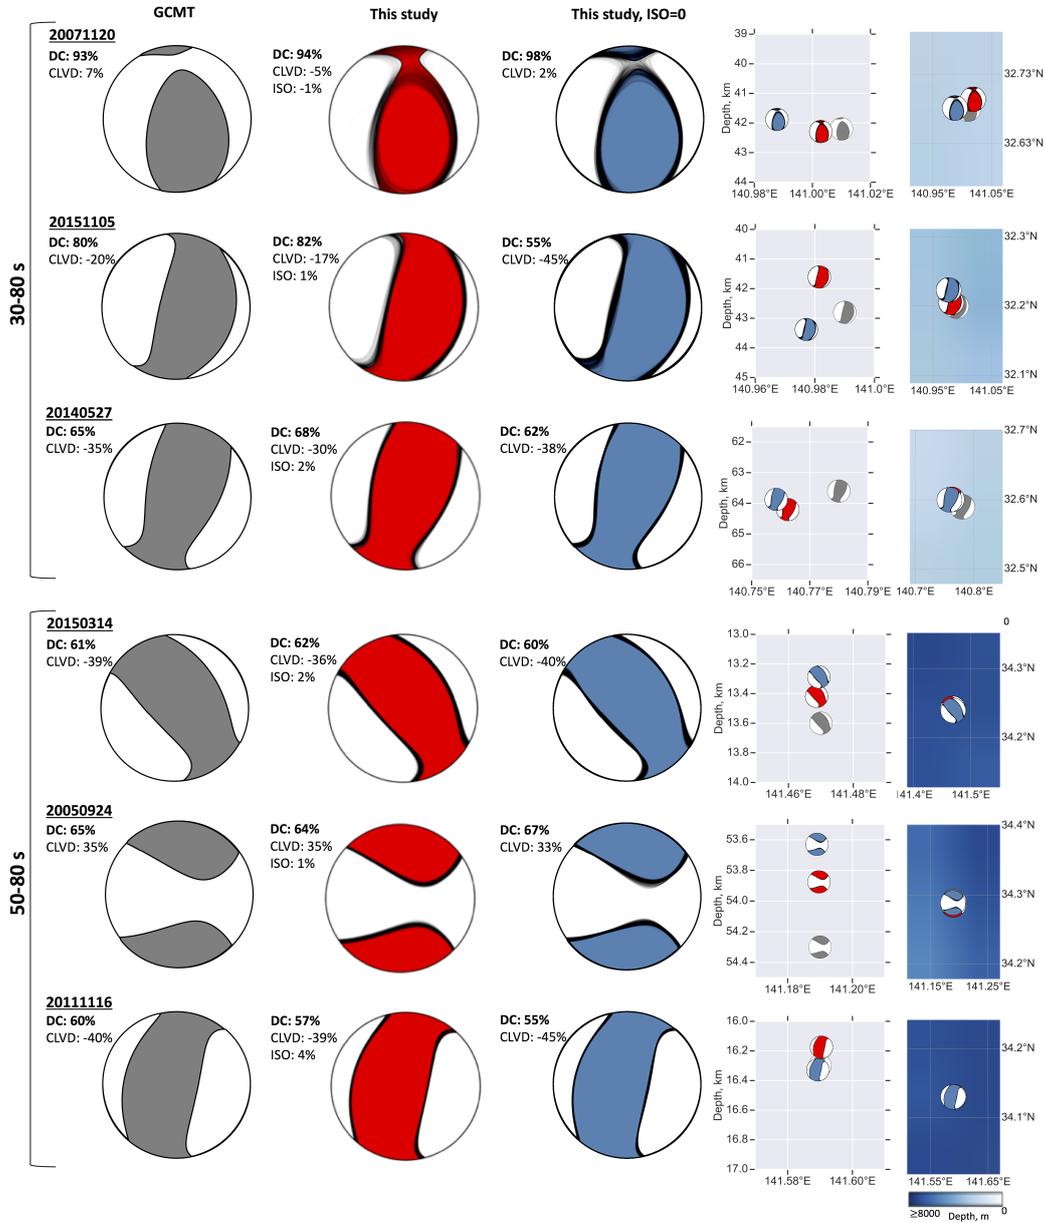

812 In this conceptual study, we detailed the methodology for a probabilistic source in-  
 813 version using 3-D Green's functions and presented a proof-of-concept catalog of source  
 814 solutions. Such an approach allows us to better constrain source characteristics and comes  
 815 with the ensemble statistics, such as uncertainty limits and inter-parameter trade-offs.  
 816 Inferred source parameters contribute to our understanding of the regional seismotec-  
 817 tonics and earthquake physics and can also be fed back into and, potentially, improve  
 818 tomographic studies. The method could be run in production mode for any part of the  
 819 world, for which a reliable 3-D Earth model is available.

## 820 9 Open Research

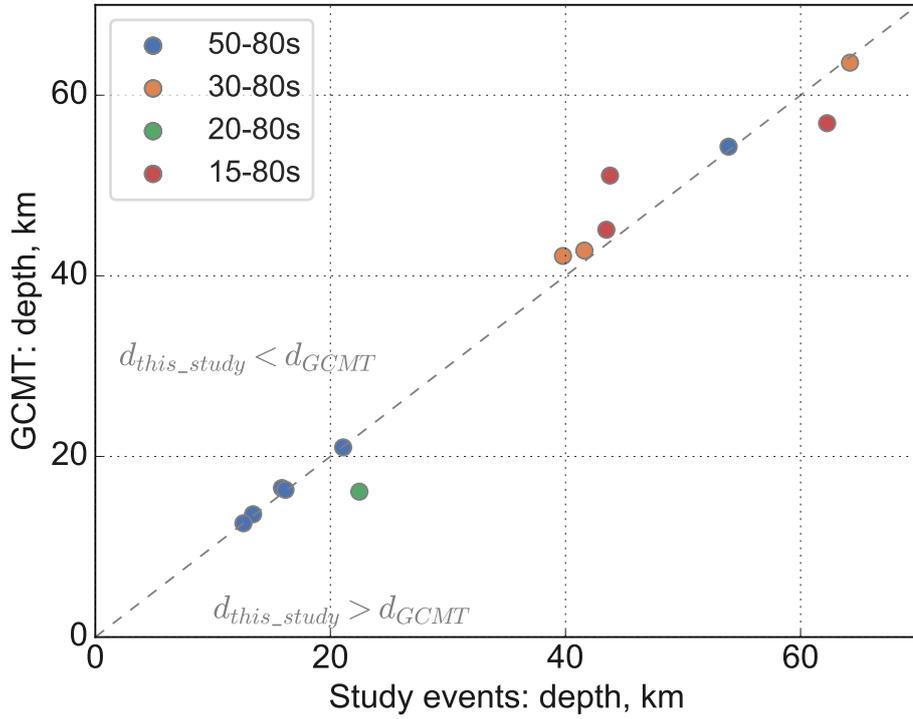

821 All seismic waveform data used in this study are freely available from the Full Range  
 822 Seismograph Network of Japan (F-Net, <http://www.fnet.bosai.go.jp>), the Broadband Ar-  
 823 ray in Taiwan for Seismology (BATS, <http://bats.earth.sinica.edu.tw>), the Korea Na-  
 824 tional Seismograph Network (<http://www.kma.go.kr/weather/earthquake/internationalist.jsp>), and the China National Seismic Network, the New China Digital Seismograph  
 825 Network, the Northeast China Extended Seismic Array, the Global Seismograph Net-  
 826 work, and the Korean Seismic Network, made available by the IRIS Data Management  
 827 Center (<http://ds.iris.edu/ds/nodes/dmc/>). The centroid moment tensors were obtained  
 828 from the Global Centroid-Moment-Tensor Catalog ([www.globalcmt.org](http://www.globalcmt.org), <http://ds.iris.edu/spud/momenttensor>)  
 829 and National Research Institute for Earth Science and Disaster Prevention Seismic Mo-  
 830 ment Tensor Catalogue (<https://www.fnet.bosai.go.jp/>). Seismic wave propagation soft-  
 831 ware, SES3D, used to model the waveforms is available on <https://cos.ethz.ch/software/production/ses3d.html>.  
 832

## 833 Acknowledgments

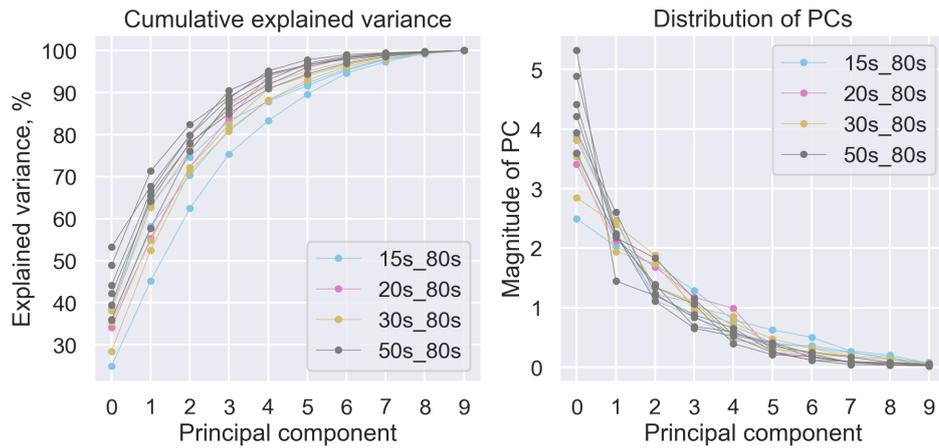

834 We express our gratitude to Göran Ekström, Andreas Zunino, Jean-Paul Montag-  
 835 ner, Pascal Bernard, and Claudio Satriano for useful discussions and insights about this  
 836 study. This work was supported by a grant from the Swiss National Supercomputing Cen-  
 837 tre (CSCS) under project ID s1040 and by the European Unions Horizon 2020 research  
 838 and innovation program through an ERC Starting Grant (The Collaborative Seismic Earth  
 839 Model, grant No. 714069).

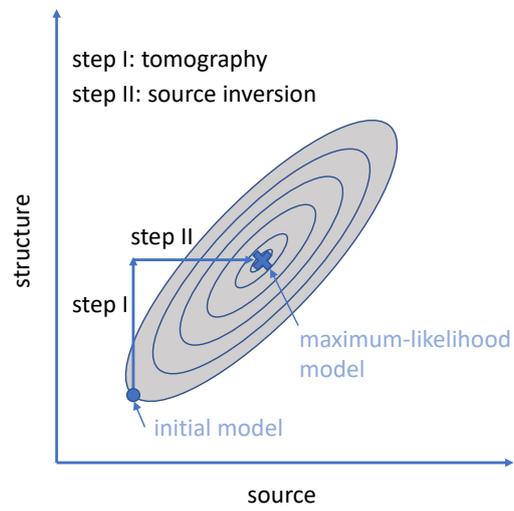

**Figure 15.** Moment tensor ensembles inferred with 30–80 s (top three) and 50–80 s period data (bottom three). Gray beachballs correspond to the GCMT solution, red beachball correspond to an unconstrained inversion, and blue ones correspond to the inversion, where we assume no volumetric component. Gray lines represent every 100th model of the ensemble, with the maximum-likelihood models colored. On the right, we show the maximum-likelihood locations, following the same color code.

**Figure 16.** Comparison of earthquake depth in GCMT and unconstrained inversion of our study, color-coded by the period band of the inversion. Events inverted with the shorter-period data tend to deviate more from the GCMT solution than those inverted with longer periods.

**Figure 17.** **Left:** cumulative explained variance with respect to the principal components of the posterior correlation matrix of all study events within their acceptable period band. **Right:** distribution of eigenvalues, or principal components of the posterior correlation matrix.
