Key Points:

- Hydrographic status update with the first comprehensive CTD survey along the entire FRIS front since 1995
- Strong and stable presence of High Salinity Shelf Water in Ronne Depression over decades
- Dominance of Ronne-sourced Ice Shelf Water in Filchner Trough in 2018 points to intensified sub-FRIS circulation

25   **Abstract**

26   The Filchner-Ronne Ice Shelf (FRIS) is characterized by moderate basal melt rates due to the

27   near-freezing waters that dominate the wide southern Weddell Sea continental shelf. We

28   revisited the region in austral summer 2018 with detailed hydrographic and noble gas surveys

29   along FRIS. The FRIS front was characterized by High Salinity Shelf Water (HSSW) in Ronne

30   Depression, Ice Shelf Water (ISW) on its eastern flank and an inflow of modified Warm Deep

31   Water (mWDW) entering through Central Trough. Filchner Trough was dominated by Ronne

32   HSSW-sourced ISW, likely forced by a recently intensified circulation beneath FRIS due to

33   enhanced sea ice production in the Ronne polynya since 2015. Glacial meltwater fractions and

34   tracer-based water mass dating indicate two separate ISW outflow cores, one hugging the

35   Berkner slope after a two-year travel time, and the other located in the central Filchner Trough

36   following a ~six year-long transit through the FRIS cavity. Historical measurements indicate the

37   presence of two distinct modes, in which water masses in Filchner Trough were dominated by

38   either Ronne HSSW-derived ISW (Ronne-mode) or more locally-derived Berkner-HSSW

39   (Berkner-mode). While the dominance of these modes has alternated on interannual time scales,

40   ocean densities in Filchner Trough have remained remarkably stable since the first surveys in

41   1980. Indeed, geostrophic velocities indicated outflowing ISW-cores along the trough's western

42   flank and onto Berkner Bank, which suggests that Ronne-ISW preconditions Berkner-HSSW

43   production. The negligible density difference between Berkner- and Ronne-mode waters

44   indicates that each contribute cold dense shelf waters to protect FRIS against inflowing mWDW.

45

46 **Plain Language Summary**

47 We visited the largest floating Antarctic ice shelf in the southern Weddell Sea in 2018 with an

48 icebreaker expedition, and measured ocean temperature, salinity, meltwater content and other

49 parameters in front of the Filchner-Ronne Ice Shelf. We found that the ocean conditions were

50 still dominated by the very cold and dense waters needed to protect the ice shelf from inflowing

51 warm waters from the deep ocean. We compared the 2018 conditions with earlier surveys since

52 the 1980s and concluded that, in spite of climate change and in contrast to other Antarctic

53 regions, the water masses on the southern Weddell Sea shelf remained relatively stable overall.

54 We found that most of the stations we visited near the Filchner Ice Shelf edge were dominated

55 by cold Ice Shelf Water, which forms when water masses interact with the underside of the shelf

56 ice. Our measurements helped improve our understanding regarding the currents and water

57 masses on the southern Weddell Sea continental shelf.

58

1) Introduction

The Antarctic continent stores the largest amount of freshwater on earth. However, the Antarctic ice sheets and glaciers are losing mass, leading to a cumulative sea level rise of 14 mm since 1979 (Rignot et al., 2019). Some ice mass loss could be linked to changes in the atmosphere, such as the warming of the Antarctic Peninsula (Vaughan et al., 2003), which triggered the decay of the Larsen ice shelves (Rott et al., 1996; Broeke v.d., 2005). However, the majority of ice mass was lost from glaciers and ice sheets that were exposed to the influence of warm ocean waters (Rignot et al., 2019). Thompson et al. (2018) classify the Antarctic marginal seas into "warm", "fresh", and "dense" shelves based on their hydrographic properties impacted by the dynamics of the Antarctic Slope Current system and associated frontal dynamics. On "warm" continental shelves such as along the West Antarctic Peninsula or in the Amundsen and Bellingshausen Seas, warm waters of open ocean origin intrude inshore by following the seafloor since there is no strong front separating the shelf from the warm Circumpolar Deep Water (CDW) as is found on the "fresh" shelves surrounding the Antarctic continent. The "dense" continental shelves of the Ross and Weddell Seas are wide and dominated by near-freezing conditions (Nicholls et al., 2009) and characterized by moderate ice shelf basal melt rates (Paolo et al., 2015; Rignot et al., 2019). The Filchner-Ronne Ice Shelf (FRIS), Antarctica's largest ice shelf by volume, is located south of such a "dense" wide continental shelf in the Weddell Sea. The circulation and oceanographic conditions on this southern Weddell Sea shelf are dominated by a saline water mass named High Salinity Shelf Water (HSSW). HSSW is at surface-freezing temperature ($\sim$ -1.9 °C) and forms as a result of sea ice production on the continental shelf and in coastal polynyas, in particular in the southwestern Weddell Sea off Ronne Ice Shelf (RIS, Haid and Timmermann, 2013). HSSW has salinities of 34.60-34.85 and contributes to the dense shelf waters or directly flows off the shelf across the continental slope and contributes to the formation of Weddell Sea Deep and Bottom Waters (Gordon et al., 1993; Orsi et al., 1999), which are precursors of Antarctic Bottom Water (AABW). Data from moorings at the ice shelf front (Nicholls et al., 2004), sub-ice shelf moorings (Nicholls et al., 2001), and model studies (Timmermann et al., 2012) indicate that HSSW enters the cavity below FRIS following the bathymetry in Ronne Depression and drives an ice shelf-wide thermohaline circulation (Figure 1). En route through the cavity, HSSW may encounter greater water pressures that lower the in situ freezing point to match its own surface-freezing temperature, thereby causing melting at the

90 base of the ice shelf (model-derived average of 0.34 m year^{-1} at FRIS; Timmermann et al., 2012).

91 The resulting modified water mass is colder and fresher and hence more buoyant and is referred

92 to as Ice Shelf Water (ISW). ISW is characterized by below-surface freezing temperatures (< -

93 1.9°C), and leaves the FRIS cavity via the Filchner Trough (Nicholls et al. 2009).

94 These cold and dense waters prevent a large-scale inflow of Warm Deep Water (WDW), the

95 Weddell Sea's derivative of CDW, which occupies the intermediate layer (200-1200 m) of the

96 Weddell Sea (Daae et al., 2020). This is not the case along the narrow continental shelf off

97 Dronning Maud Land, where WDW mixes with the colder and fresher Eastern Shelf Water to

98 result in modified (m)WDW, which seasonally penetrates the southern Weddell Sea through

99 troughs intersecting the continental shelf (Ryan et al., 2017). The seasonal flow of mWDW onto

100 the shallower shelf is regulated by the Antarctic Slope Front, which responds to changes in the

101 wind field and stratification (Hattermann, 2018) and controls cross-frontal exchange through

102 mesoscale eddies and instabilities (Nøst et al., 2011; Stewart and Thompson, 2015; Stewart et al.,

103 2018). On FRIS, however, the impact of mWDW is presently limited by the cold, dense waters

104 that occupy the Filchner Trough, though model studies suggest that a freshening of the shelf

105 water masses under warmer atmospheric conditions may lead to enhanced warm water inflow

106 and dramatic ice shelf melting by the end of this century (Hellmer et al., 2012; Hellmer et al.,

107 2017; Daae et al., 2020). MWDW is a persistently observed water mass at the RIS front, west of

108 Berkner Bank (Foldvik et al., 2001; Gammelsrød et al., 1994), and also has been observed at the

109 FIS front (Darelius et al. 2016). Recent moored temperature records indicate considerable

110 interannual variability of mWDW-presence in Filchner Trough (Ryan et al., 2020). At present,

111 this does not appear to significantly contribute to FRIS mass loss, as mWDW resides above the

112 depth of the ice shelf front atop denser waters that occupy the Filchner Trough. However, future

113 melt rates will crucially depend on the evolution of the dense water masses and circulation on the

114 southern Weddell Sea continental shelf.

115 Prior to 2017, the hydrography at Filchner Ice Shelf (FIS) front was dominated by water

116 masses that were formed on Berkner Bank (Figure 1), referred to as Berkner-HSSW (Akhoudas

117 et al. 2020), and seasonal outflows of ISW along the western flank of the trough (Darelius and

118 Sallée, 2018). However, temperature and salinity records from moorings underneath FRIS have

119 shown an intensification of the Ronne-HSSW driven cavity circulation in response to increased

120 sea ice formation in the Ronne Polynya since 2015. This resulted in a decline in Berkner-HSSW

121   and an increase in Ronne HSSW-derived ISW in the Filchner Trough in mid-2017 (Hattermann

122   et al., 2021, from here on referred to as H2021). Shortly thereafter, in austral summer 2018, an

123   *RV Polarstern*-expedition (PS111) was able to access both FIS and RIS fronts during extended

124   polynya events and undertake a detailed hydrographic survey.

125   In this paper, we present a 2018 hydrographic status update of the FRIS front and

126   Filchner Trough, and contrast our findings with those from earlier expeditions. Further, we

127   investigate the variability of circulation regimes underneath FRIS as inferred from observed

128   ocean conditions in Filchner Trough. Specifically, we discuss two contrasting circulation modes

129   that are immediately connected to HSSW production north of RIS and on Berkner Bank, referred

130   to as Ronne- and Berkner-modes. We examine these modes in a historical context and finally

131   discuss the impact of changes in forcing parameters on the regional and large-scale ocean
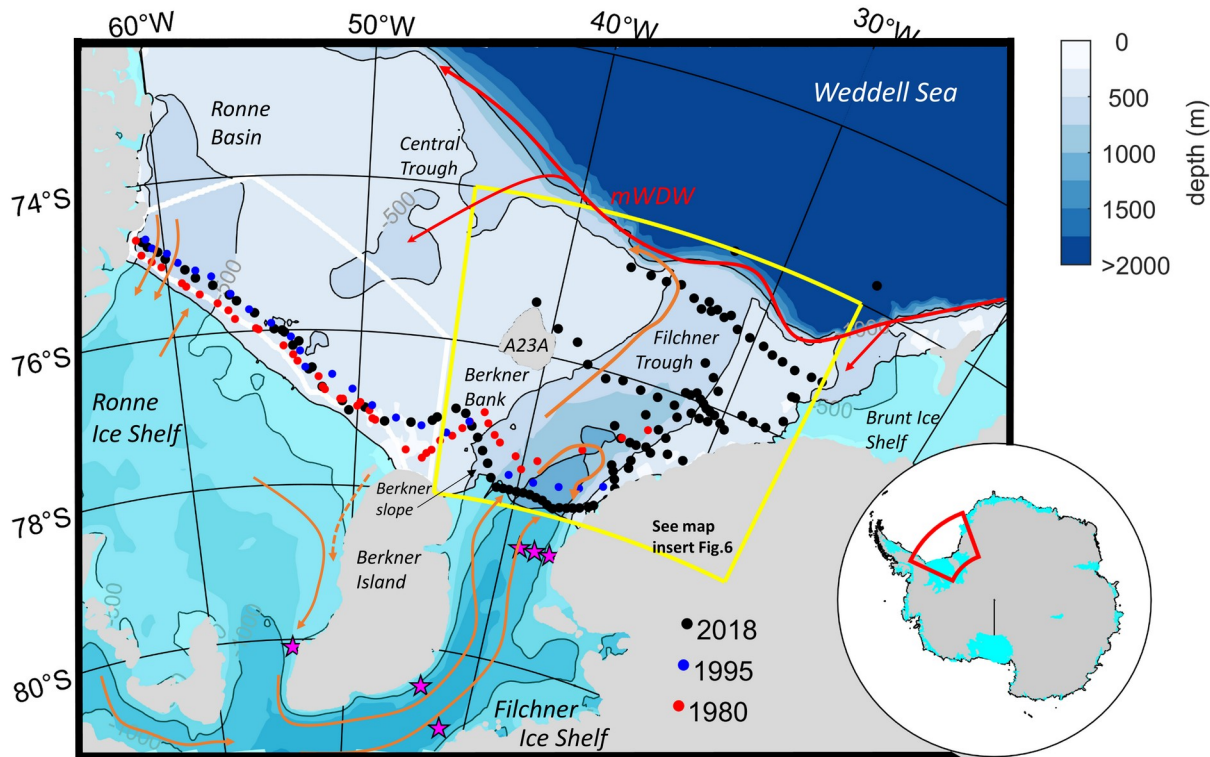

132   circulation.

142

143 **2) Materials and Methods**

144 <u>2.1 Hydrographic data</u>

145   Hydrographic measurements were carried out onboard the German research icebreaker *RV*
146 *Polarstern* (Alfred-Wegener-Institut Helmholtz-Zentrum für Polar- und Meeresforschung, 2017)
147 during the PS111-expedition to the southern Weddell Sea (Figure 1) from 12 January to 14
148 March 2018 from Cape Town, South Africa, to Punta Arenas, Chile. Temperature and salinity
149 profiles during PS111 (Janout et al., 2019) were collected with a Seabird 911+ CTD
150 (Conductivity-Temperature-Depth) recorder attached to a water sampling carousel. The raw data
151 were processed with the Seabird processing software and quality controlled thereafter. Pre- and
152 post-cruise calibrations of the conductivity and temperature sensors were performed by the
153 manufacturer. Finally, the salinity values were corrected with salinity measurements from water
154 samples, which were measured with an Optimare Precision Salinometer. The final accuracies of
155 the CTD data are estimated as 0.0005°C and 0.002 for temperature and salinity, respectively.
156 Dissolved oxygen measurements were collected with an oxygen sensor attached to the CTD. The
157 sensor was carefully calibrated throughout the expedition by measuring the oxygen content of
158 water samples using the Winkler titration method. Along-track oceanographic and
159 meteorological parameters were measured with *RV Polarstern*'s fixed installed underway
160 measurement system. Temperature and conductivity at 11 m (Figure 2a-b) were measured with a
161 thermosalinograph SBE21 (Schröder and Rohardt, 2018) with accuracies of 0.001°C and 0.001
162 S/m. Air temperature, wind speed and direction, and atmospheric pressure (Figure 2c-f) were
163 measured with Polarstern's weather system (Schmitthüsen, 2020).

164   Geostrophic velocities were computed from the density structure measured via CTD stations
165 along FRIS assuming a level-of-no-motion at 200 m as this is the minimum thickness of the edge
166 along FRIS (Schaffer et al., 2016). In order to distinguish between ISW sourced from either
167 Ronne- or Berkner-HSSW, we defined the respective source water salinities by finding the
168 crossing point of the ISW Gade line (Gade, 1979) with the surface freezing temperature line.
169 This method assumes water mass transformation along characteristic lines in temperature-

170 salinity-space in the absence of other mixing end members. We neglected the effect of heat
171 conduction at the ice shelf-ocean interface and used a slope of 2.4 K/psu of the Gade line,
172 resulting from $\Delta T/\Delta S = L/(S_0 c_p)$, where the latent heat of ice is $L = 3.34 \times 10^5$ J kg^{-1} , the specific
173 heat capacity of seawater cp= 4186 J kg^{-1} K^{-1}, and S_0 is the seawater salinity.

174   We revisited earlier hydrographic stations to view the 2018-observations in a decadal context
175 and to understand the variability in hydrographic properties and tracers along the FRIS front.
176 Prior to 2018, the most comprehensive surveys along FRIS took place in 1980 (early January to
177 mid-February) aboard the *RV Polarsirkel* (Gammelsrød and Slotsvik, 1981) and in 1995 (late
178 January to early March) aboard *RV Polarstern* (Schröder, 2010). We use CTD stations from both
179 earlier surveys and in addition tracer data from 1995. Similar to PS111, both historic surveys
180 entered the Ronne ice front region through polynyas, and CTD stations were approximately
181 sampled at the same relative distance from the shelf ice. For an interannual comparison of source
182 water salinities in Filchner Trough, we further investigated historical CTD stations collected
183 between 1973 and 2018 (see Carmack and Foster, 1975; Foldvik et al., 1985; Driemel et al.,
184 2017 for historic data details).

185

186 2.2 <u>Glacial basal melt water (GBMW) from oceanic noble gas measurements</u>

187   Water samples from the CTD-rosette-system were collected in gas tight copper tubes and
188 subsequently analyzed for noble gas content with the IUP Bremen mass spectrometer (Sültenfuß
189 et al, 2009). Oceanic measurements of the low-solubility and stable noble gases helium (He) and
190 neon (Ne) provide a useful tool to identify and quantify GBMW (e.g. Schlosser et al. 1986;
191 Hohmann et al., 2002; Huhn et al., 2008; Huhn et al., 2018; Rhein et al, 2018). Atmospheric air
192 with a constant composition of these noble gases is trapped in the ice matrix during formation of
193 the meteoric ice. Due to the enhanced hydrostatic pressure at the ice shelf base, these gases are
194 completely dissolved in the water when the ice melts. This leads to a He concentration of 25.7
195 nmol/kg and a Ne concentration of 90.1 nmol/kg in pure GBMW (Loose and Jenkins, 2014).
196 GBMW is detectable at fractions of <0.05% based on an accuracy of <0.5% for He
197 measurements performed at the IUP Bremen. Some GBMW may be enriched with crustal He
198 (i.e., the isotope ^{4}He) from α-decay of uranium, thorium, and their daughter products in the
199 bedrock beneath an ice sheet. On geological timescales, the crustal He accumulates in the
200 overlying ice up to 300 m above the bedrock (Beaird et al., 2015; Suess and Wänke, 1963). A He

201   surplus of 4.5 ± 0.5 times that of GBMW has been observed in deep ice near to bedrock. Some
202   He (mainly primordial ^{3}He) is released by mid-ocean ridges to the ocean's interior by
203   hydrothermal activity (Clarke et al., 1969; Well et al., 2003), increasing the ^{3}He/^{4}He ratio
204   (expressed as δ^3He in %) in the water versus the equilibrium ratio. We used the He and Ne
205   concentrations and the method from Rhein et al. (2018) to calculate the fractions of GBMW.
206   First, we estimated the mean mixed layer supersaturation from noble gas stations at a distance
207   from the ice shelf front (to avoid bias from upwelled GBMW into the mixed layer) and
208   subtracted this value from the measured values. Then, we subtracted the equilibrium value
209   He$_{EQ}$(θ,S) and Ne$_{EQ}$(θ,S) (for each data point as a function of the local potential temperature θ
210   and salinity S using the solubility function from Weiss (1971)) from the observed values and
211   attributed the remainder to pure GBMW. In this paper, we show GBMW calculated from Ne to
212   exclude any bias from additional crustal He.

213   Additionally, we analyzed 335 seawater samples for the transient tracers chlorofluorocarbon
214   CFC-12 and sulphur hexafluoride SF$_6$. These anthropogenic trace gases have increased in the
215   atmosphere due to rising human production and enter the ocean via gas exchange at the ocean
216   surface. Hence, they allow us to determine transit time scales of oceanic transport (Smethie et al.,
217   2001; Waugh et al., 2003; Huhn et al., 2013). Samples were filled from the CTD-rosette-system
218   into glass ampoules avoiding atmospheric contact. The ampules were flame-sealed after a tracer-
219   free headspace of purified nitrogen was applied. Later, at IUP Bremen, the samples were
220   analyzed by purge and trap pre-treatment followed by gas chromatographic (GC) separation on a
221   capillary column and electron capture detection (ECD) (Bulsiewicz et al., 1998). The total error
222   of the measurement was ± 2 % for CFC-12 and ± 5 % for SF$_6$. Here, we show the partial pressure
223   of these trace gases in the samples instead of concentration to account for the solubility of these
224   gases under different temperatures and salinities (Warner and Weiss, 1985; Bullister et al.,
225   2002).

226   Water mass ages (i.e. the time lag between the last contact with the atmosphere and time of
227   observation) were determined from the ratio of SF$_6$/CFC-12. The ratio excludes the effect of
228   mixing with old (tracer-free) water and possible saturation dis-equilibria during formation
229   (assuming identical equilibration fractions for both tracers). First, we calculated the partial
230   pressure of these gases in each sample from the concentrations, temperature and salinity using
231   the solubility functions from Warner and Weiss (1985) and Bullister et al. (2002). Second, we

232   compared the partial pressure ratio in each sample with the known atmospheric ratio time history

233   (Bullister, 2017), and determined the year of equilibration with the atmosphere and finally the

234   age as the time lag between year of observation and formation.

235   2.3 Ronne sea ice production estimates

236   The highest sea ice production rates in the southern Weddell Sea are found in coastal

237   polynyas, areas characterized by open water, thin ice, and low sea ice concentration (Paul et al.,

238   2015). Coastal polynyas form all along FRIS, driven by offshore winds and tides. We used

239   results from a simulation with the global Finite Element Sea ice–ice shelf–Ocean Model

240   (FESOM, Timmermann et al. (2012), Wang et al., 2014) to derive sea ice production estimates in

241   polynyas associated to the Ronne sector (white framed area in Figure 1) in the southern Weddell

242   Sea (1985-2017). The model was run on a grid with horizontal resolution that varied between 3

243   km under the ice shelves, 6-7 km along Ronne Ice Front, and up to 25 km north of the Weddell

244   Sea continental shelf. We used a hybrid vertical coordinate system with 36 layers. Ice shelf draft,

245   cavity geometry, and global ocean bathymetry were prepared from the 1-minute version of

246   RTopo-2 (Schaffer et al., 2016). This model was initialized in 1979 from temperature and

247   salinity derived from the World Ocean Atlas 2009 (Levitus et al., 2010), and run until the end of

248   2017 using atmospheric forcing from the ERA-Interim reanalysis (Dee et al., 2011) on a 75 km

249   horizontal grid, with 6-hourly air and dew point temperatures (both at 2 m altitude), 10 m-wind

250   fields, as well as 12-hourly average shortwave and longwave radiation, precipitation and

251   evaporation values. We calculated cumulative annual ice production within polynyas in the

252   Ronne sector (Figure 1) from the daily data. Only positive sea ice production rates were taken

253   into account, and nodes with sea ice concentration <70% or thickness <20 cm were considered to

254   be polynyas.

255   **3) Results**

256   3.1 Surface hydrography on the southern Weddell Sea shelf in February 2018

257   In February 2018 the near-surface (11 m) southern Weddell Sea shelf water was

258   characterized by predominantly cold and saline conditions, with average along-track temperature

259   and salinity of -1.6°C and 33.9, respectively (Figure 2). During the sampling period, heavy sea

260   ice conditions in the southern Weddell Sea inhibited access to the slope region west of ~36°W.

261   However, extensive open water regions were found in a large polynya along the eastern Filchner

262   Trough and near the shelf break in the northeast, where maximum temperatures of -0.8°C were

263   measured in early February. The warm temperatures then vanished during the second visit to the

264   region in late February, with the sea ice cover rapidly closing under freezing air temperatures

265   (Figure 2c) during the transition to winter conditions. Southwest of the grounded iceberg *A23A*

266   (Figure 2), an extended region with decreased sea ice concentration, which had been apparent

267   since November 2017 (not shown), developed into open water by February 2018. This region

268   (45-50°W) is within the mWDW-inflow region along Central Trough that will be discussed in

269   more detail later, and showed above-freezing surface waters of -1.3°C during our transit on 10

270   February 2018 (Figure 2a). Tides are considerable on the southwest Weddell Sea shelf

271   (Makinson, 2002) and likely cause upward heat fluxes of the mWDW to the surface, which may

272   contribute to the local reduction in sea ice concentration there. All other regions along the cruise-

273   track featured near-freezing surface waters. In particular, the westernmost track along RIS was

274   carried out along a narrow (~5-10 km) polynya caused by southerly winds before and during our

275   visit in early-to-mid February 2018 (Figure 2d-e), which led to active sea ice formation with

276   minimum air temperatures reaching below -20°C (Figure 2c) during the time of our observations.

277   Surface salinities showed considerable gradients from the northeast to the southwest (Figure 2b).

278   The northeast is influenced by local and advected meltwater with minimum salinities of 33.5 and

279   slightly higher values of up to 34.0 toward the FIS edge. Maximum surface salinites of 34.5 were

280   found in front of RIS.

288

289

290 3.2 <u>Hydrographic conditions along the Filchner-Ronne Ice Shelf edge and in Filchner</u>
291   <u>Trough in 2018</u>

292 The hydrography along the RIS front in austral summer 2018 was dominated by HSSW with

293 salinities of up to 34.84 in the deepest part of Ronne Depression (Figure 3a-b). The overlying

294 water column was salinity-stratified with temperatures near the freezing point from surface to

295 bottom. Thermohaline measurements indicated the presence of an ISW core located on the

296 eastern flank of Ronne Depression carrying temperatures of -2.1°C. Furthermore, the ISW

297 sampled was found to possess high levels of ΔHe and ΔNe (not shown) and was thus enriched in

298 GBMW (0.8 %, Figure 4a). Geostrophic velocities suggested a 1-5 cm s⁻¹ northward flow (Figure

299 5). Another previously identified outflow branch (Nicholls et al., 2004) appeared on the western

300 edge of this transect at 60°W, although without super-cooled waters and only slightly enriched in

301 GBMW (0.5%, Figure 4a). The hydrography further east near Berkner Bank around 52°W was

302 characterized by the inflow of -1.5°C-mWDW that was guided from the shelf break toward the

303   ice shelf front along Central Trough (Figure 1). The mWDW present at the continental slope was

304   significantly warmer than the -1.5°C-waters observed at the ice shelf edge (i.e. the maximum

305   temperature in transect number 4 in Figure 6 was -0.2 °C), which suggests that a substantial

306   amount of mWDW-heat was lost during the ~500 km-long route across the southern Weddell

307   Sea shelf. The inflow had a geostrophic velocity core of ~5 cm s^{-1} and was characterized by the

308   highest δ^3He -rates observed in the transect (not shown). δ^3He quantifies the contribution of

309   mantle Helium from mid-ocean ridges in a water mass such as CDW and its derivatives (Well et

310   al., 2003; Ryan et al., 2016), thus underlining the deep-water source of the mWDW.
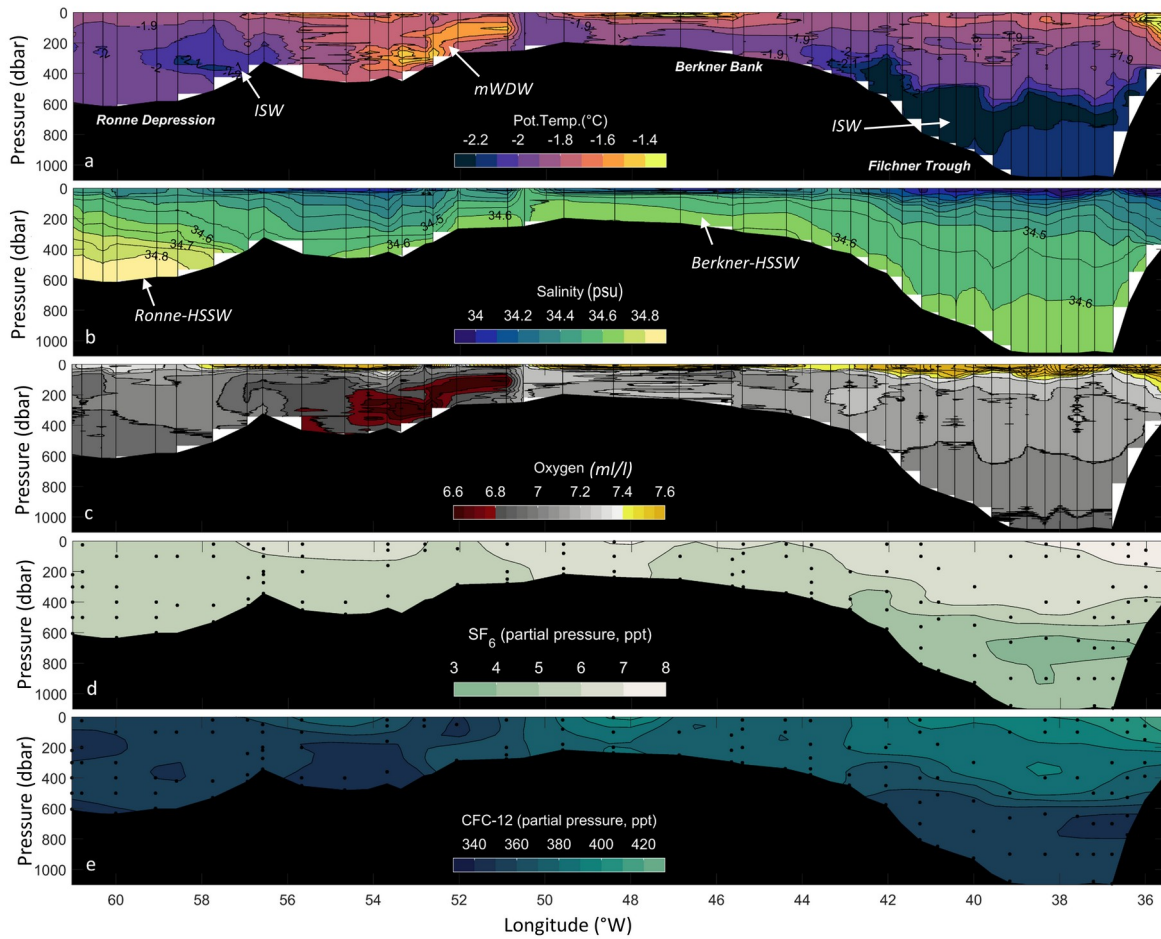

311

312

Figure 3: Properties along the FRIS front in austral summer 2018: a) potential temperature (°C), b) salinity; c) oxygen (ml/l); d) SF6 (ppt), and e) CFC-12 (ppt). Station locations can be found in Figure 1 and are indicated by vertical black lines in panels a-c and by black dots in panels d-e. Objective mapping was used to interpolate between stations in panels d and e.

317

318   Filchner Trough was strongly dominated by ISW extending across its entire width, with a

319   minimum temperature of <-2.2°C (Figure 3a) leaning against and encroaching up the western

320   flank between depths of 300-900 m. The ISW core contained salinities of 34.55-34.60 and

321   agreed with a well-defined outflow core of 1-5 cm s^{-1} (Figure 5). Noble gas tracers were highly

322   enriched in the western flank's ISW-outflow, presenting the highest ΔHe and ΔNe values (not

323   shown) found along the FRIS front, containing as much as 1% GMBW (Figure 4a). Another

324   outflow is seen against the eastern flank (Darelius et al., 2014a), which has been hypothesized to

325   be associated with eastward propagation of the ISW plume parallel to the FIS front due to the

326   step induced by the ice shelf edge and related vorticity constraints (Darelius and Sallée, 2018).

327   However, drillhole moorings roughly 60 km south of the FIS edge show the existence of a

328   northward flowing branch of this water mass along the eastern flank of the cavity (H2021). The

329   upward-sloping isohalines against the eastern flank (Figure 3b) and resulting geostrophic

330   velocities (Figure 5) suggest an inflowing undercurrent below the outflow at around 600 m,

331   which is consistent with recirculating ISW and Berkner-HSSW in Filchner Trough (Carmack and

332   Foster, 1975). The surface layer showed warmer (~ -1.3°C) waters extending from the eastern

333   corner of the transect, along with lower salinities (<34.0). These waters result from summertime

334   warming and sea ice melt, possibly fed by the coastal current that enters the area from Brunt Ice

335   Shelf (Nicholls et al., 2009). In this region, the oxygen content was the highest (7.6 ml l^{-1}) along

336   the FRIS front (Figure 3c), and indicates a recent interaction of these waters with the

337   atmosphere. This is further supported by the highest CFC-12 and SF$_6$-values found throughout

338   the transect (Figure 3d,e). The lowest oxygen content of 6.6 ml l^{-1} was found in the mWDW-

339   inflow (Figure 3c, 50-55°W), which reflects the greater age of these deep and poorly-ventilated

340   waters (Hoppema et al., 1997). HSSW-oxygen content was slightly (by ~0.1 ml l^{-1}) lower than

341   that of ISW, which is explained by the oxygen enrichment of the ISW during ice shelf melting

342   due to air trapped inside the ice. Since, however, the air trapped in the shelf ice was of a pre-

343   industrial age, it did not include any anthropogenic tracers, thus explaining the low trace gas

344   levels in the ISW (Figure 3d,e). Overall, the hydrography, along with oxygen and noble gas

345   tracers, confirmed the previously established circulation scheme at the FRIS front (Nicholls and

346   Østerhus, 2004). The dominant characteristics included the HSSW inflow at 59-60°W (although

347   the density structure did not suggest such inflow at the time of survey) and the ISW outflow

348   centered at 58°W at RIS, and the more significant ISW presence with well-defined outflow cores

349   at FIS including the highest GBMW fractions of 1.0%.

355   **ure 5: Geostrophic velocities referenced to 200 m (in cm s[-1]) along FRIS. Positive values indicate northward**
356   **flow, i.e. into the page.**

357

358   Additonal temperature and salinity transects across the northern parts of Filchner Trough

359   and sill indicated the northward extent of the ISW upon exiting from beneath the ice shelf

360   (Figure 6). While the coldest ISW of <-2.2°C dominated at the FIS front (transect 1), the eastern

361   and western slopes of the northern Filchner Trough (transect 2 and 3) showed only traces of -

362   2.1°C-waters, indicating that the northward branch of the ISW circulation cell may be found

363   there (Figure 1). Overall, at depths below 400 m, Filchner Trough was entirely occupied by ISW

364   with temperatures of -2.0°C and salinities of >34.55, except for a more saline (34.60-34.65) near-

365   bottom layer (10s of meters thick) that was just below the freezing point (Figure 7). These

366   densest bottom waters circulate in Filchner Trough and result from a mixture of HSSW formed

367   on Berkner Bank with the ISW outflow from underneath FIS. Most of these waters are too dense

368   to spill northward over the ~500 m-deep sill separating Filchner Trough from the deep Weddell

369   Sea and will thus remain confined to Filchner Trough. The overflowing waters observed north of

370   the sill (Figure 6, transect 4) are characterized by slightly lower density of ~0.05 kg m^{-3} (Figure

371   7) and thus originate from the ISW layer of -2.1 to -2.0°C that occupy the 400-700 m depth

372   layers (transect 3). The cold overflow in transect 4 was overlain by mWDW with maximum

373   temperatures of almost 0°C and salinities of 34.5-34.6. The upward-sloping isohalines indicate

374   enhanced northward transport at the western side of the transect, while the stations east of 31°W

375   featured mWDW all the way to the bottom. The 2018 water mass distribution in the northern

376   trough resembled conditions similar to those observed during earlier expeditions, as for example

377   in 2003 (e.g. Darelius et al., 2014b). The easternmost station in transect 4 showed ISW with a

378   lower salinity of 34.3 (Figure 7), which points to a shallower source from underneath Brunt Ice

379   Shelf.

380

401

4) Discussion

403

4.1 Decadal variability in front of Ronne Ice Shelf

405   Sea ice conditions during early 2018 allowed us to survey the water masses of a ~750 km-
406   long stretch along the FRIS front with unprecedented spatial resolution. Only a few expeditions
407   have been able to access both FIS and RIS, though not with the high spatial resolution sampling

408   grid that was accomplished during PS111. Two such similar expeditions were carried out in

409   austral summers of 1980 and 1995 and allow for a comparison across a four-decade time period.

410   Similar temperature and salinity features to those shown in Figure 3 are evident in all three

411   surveys, although the station coverage was not as spatially dense in the historic surveys. The

412   minor thermohaline differences are therefore best displayed and compared using temperature-

413   salinity-diagrams (Figure 8). Minimum temperatures of –2.25°C recorded in 2018 were as low as

414   in 1980, and only marginally warmer in 1995 (Figure 8a). Salinities at the ISW temperature

415   minimum were slightly (~0.02 psu) lower in 2018 compared with the other two periods in

416   Filchner Trough (Figure 8c). In Ronne Depression, HSSW prominently appeared in all three

417   surveys, with maximum salinities in 1995 and 2018 of >34.80, and slightly lower maximum

418   salinities in 1980 of 34.78 (Figure 8b). The minimum temperature in the ISW outflow at 58°W in

419   2018 was -2.1°C and thus slightly lower than the other two years. This is consistent with slightly

420   higher GBMW fractions of 0.7% in 2018 compared with 0.5% observed in 1995 inside the ISW

421   outflow (Figure 4). The inflow of mWDW along Central Trough existed in all surveys with

422   minor temperature differences between these years. However, the mWDW inflow is remotely

423   controlled by slope front dynamics (Daae et al., 2017). This is further underlined by moored

424   temperature records near the ice shelf front at 53°W, which showed considerable seasonal and

425   interannual variability in the water mass properties (Foldvik et al., 2001), similar to the

426   variability reported for the Filchner Trough mWDW inflow (Ryan et al., 2020). Therefore,

427   observed differences between CTD snapshots can arise from the surveying point in time and
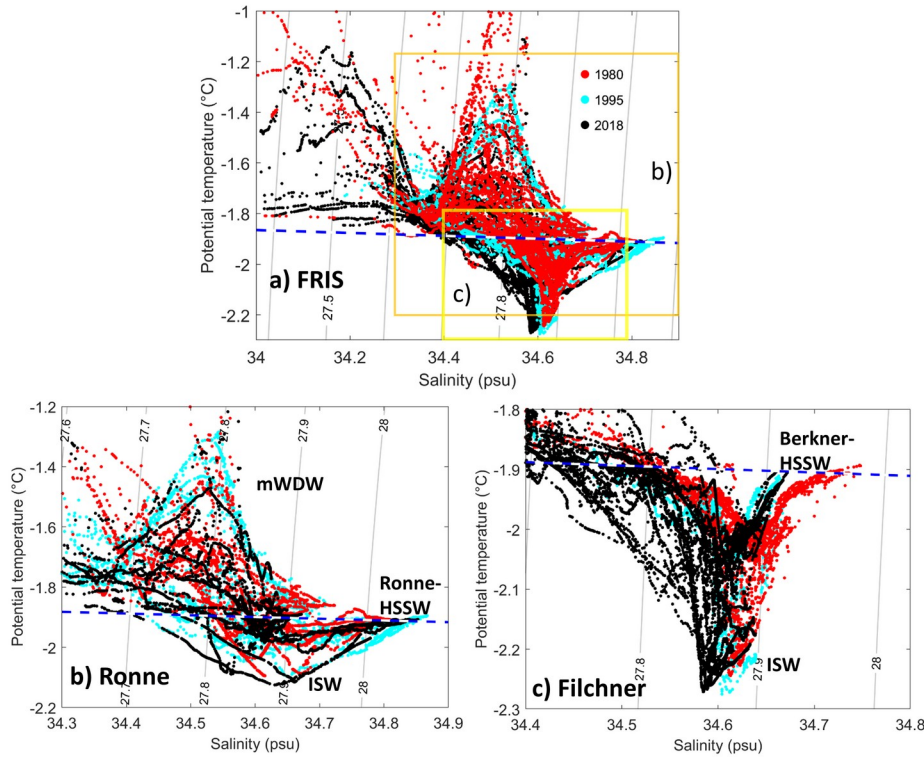

428   should not be overemphasized.

429
Figure 8: a) Temperature-salinity-diagram from all CTD stations along FRIS, b) from Ronne (west of 50°W),
and c) Filchner (east of 43°W) CTD stations from 1980 (red), 1995 (cyan) and 2018 (black). Station locations
are shown in Figure 1. σ_0–contours are shown in black lines in 0.1 kg m^{-3}-increments. The dashed line
indicates the surface freezing temperature. Yellow boxes in panel a) indicate the temperature-salinity-
properties of panels b) and c).

435

436   The conditions in front of RIS remained remarkably constant over time, despite the effect of

437   the grounded icebergs after 1987 (Nøst and Østerhus, 1998; Grosfeld et al., 2001). Flow features

438   likely stayed in the same locations due to topographic steering of the currents. One explanation

439   for the relatively stable hydrography there may be that sharp salinity gradients developed during

440   strong polynya events can lead to baroclinic instabilities (Chapman and Gawarkiewicz, 2003;

441   Jenkins et al., 2004), which mix excess HSSW salt patches either into the cavity or northward.

442   The ISW-outflow on the eastern flank of Ronne Depression is the northward extension of the

443   sub-ice shelf circulation observed by Nicholls et al. (2004) and a comparatively small but

444   constant feature, with most of its core at -2.0°C. The "warm" ISW temperature indicates that the

445   HSSW-modification took place at a shallow ice shelf base (i.e. not far inside the cavity) with

446   only a slightly lowered freezing point relative to the surface. The GMBW fractions are only

447   slightly elevated in both 1995 and 2018 (0.5-0.7%) (Figure 4), and the tracer-based water mass

448   dating indicates that the ISW is only 1-2 years older than its Ronne-HSSW source water (Figure

449   9). The ISW mixes with the adjacent waters soon after exiting RIS and is no longer observed as a

450   distinct water mass on the southwestern Weddell Sea shelf (Nicholls et al., 2004). Earlier

451   mooring records from the RIS front show flow parallel to the ice front, which was explained by

452   blocking due to denser HSSW and northwestward diversion of the ISW outflow parallel to the

453   RIS edge (Foldvik et al., 2001; Nicholls et al., 2004). Ronne Depression is the deepest part of the

454   not-ice shelf-covered southwestern Weddell Sea shelf (Figure 1) and thus collects all dense

455   waters formed in front of RIS. Therefore, each late summer hydrographic CTD snapshot along

456   RIS samples the accessible remains of a reservoir with flushing time scales of roughly 10 years

457   (Huhn et al., 2018). These long time scales explain the remarkably stable hydrography along RIS

458   and hence provide only limited information regarding the processes taking place underneath

459   FRIS. The anthropogenic tracer-based dating in front of RIS at 58-60°W determined the HSSW

460   water mass age to be 4-6 years old (Figure 9), which may be partly due to older recirculating

461   ISW on the eastern flank of Ronne Depression (Figure 3a). The old water mass age supports the

462   concept that these winter-formed waters pool and contribute to a stable long-term reservoir

463   without swiftly changing conditions. Apart from difficult sea ice conditions in the southwestern

464   Weddell Sea that often inhibit ship-based access, our conclusions suggest that frequent surveys

465   of the RIS edge region may not be needed due to the long time scales. However, since HSSW-

466   production varies interannually and the associated volume transports into the cavity drive the

467   circulation underneath FRIS, as will be discussed in the following, it would be desirable to

468   obtain time series measurements of volume transports across the RIS front.

469
470   **Figure 9: Water mass age based on the SF6/CFC12-ratio (see data and methods section) along the FRIS front.**
471   **The bathymetry is based on station depth inferred from CTD profiles. Data are interpolated between the data**
472   **points (black dots) and displayed in 1 year-color contours. ISW outflows are marked with white arrows.**
473

474
475 **Figure 10: Temperature-salinity-diagram from CTD stations along FRIS. Colors differentiate between Ronne**
476 **(blue), Berkner (red) and Filchner (green) stations. The blue star marks the mean temperature and salinity of**
477 **ISW colder than -2.1°C including the standard deviations indicated by the vertical and horizontal lines. The**
478 **Gade lines bound possible source water salinities (without considering mixing) at the intersection with the**
479 **line of surface freezing points (black dashed line). The Gade lines neglect the effect of heat conduction into**
480 **the ice and use a slope of 2.4 K/psu.**
481

482   4.2 On the hydrographic transition between 2017 and 2018 at the Filchner Ice Shelf front

483   The most striking feature during our 2018-survey in Filchner Trough was the large ISW-

484 covered cross-area with temperatures of <-2.2°C (Figure 3a, Figure 6 transect 1). Well-defined

485 ISW cores at similar temperatures were seen in earlier surveys, such as in 1973 (Carmack and

486 Foster, 1975), 1980 (Foldvik et al., 1985) or 2017 (Darelius and Sallée, 2018). However, these

487 ISW cores were limited to the western flank, while in 2018 the ISW below -2.2°C was found

488 across the entire width of Filchner Trough. The source of the ISW observed in the trough can be

489 inferred by applying Gade lines (Gade, 1979) in a temperature-salinity diagram. Following

490 Hutchinson et al. (2020), we applied the Gade lines based on the mean temperature and salinity

491 of the waters below -2.1°C and their standard deviations (Figure 10). The Gade line with a slope

492 of 2.4 K/psu traces the observed ISW temperatures to the surface freezing temperature and

493   identifies a range of resulting source salinities of 34.7-34.75. This is lower than the observed

494   maximum Ronne-HSSW salinities of 34.84 but more saline than any other water mass sampled

495   along FRIS. Considering that HSSW flowing underneath RIS enters a tidally-energetic

496   environment (Makinson, 2002; Makinson and Nicholls, 1999) and mixes with local water masses

497   of likely lower salinities, we conclude that the observed ISW in Filchner Trough could only have

498   been sourced by Ronne-HSSW.

499   The 2018-conditions contrast with those observed one year earlier in 2017, when a CTD and

500   stable isotope tracer survey found that Berkner HSSW-sourced ISW dominated in Filchner

501   Trough (Akhoudas et al., 2020). These two different hydrographic conditions are referred to as

502   Berkner- and Ronne-modes, and are mainly manifested by contrasting hydrographic conditions

503   underneath the northern FIS and in Filchner Trough, as schematically illustrated in Figure 11.

504   The two modes can also be understood as a measure of sub-FRIS circulation, forced by the

505   production of Ronne-HSSW. When Ronne HSSW-production is weak, the local Berkner-HSSW

506   dominates in the Filchner region, as observed in 2017 (Akhoudas et al., 2020), and is also able to

507   enter the northern parts of FIS (Figure 11a). In contrast, an enhanced FRIS-circulation fueled by

508   stronger inflow of Ronne-HSSW leads to enhanced ISW outflow from underneath FIS, which

509   results in the dominance of Ronne-sourced ISW along the FIS front and in Filchner Trough, as

510   observed in 2018 (Figure 11b).

511   Besides the Filchner Trough snapshot observations made in 2017 (Akhoudas et al., 2020)

512   and 2018, a transition from Berkner- to Ronne-sourced waters was observed by drillhole

513   moorings, which recorded CTD time series throughout this period at different locations

514   underneath FIS (H2021, see Figure 1 in this paper for drillhole mooring locations). As illustrated

515   in Figure 11 and shown by Figure 2 in H2021, the mooring locations deep inside the cavity only

516   feature Ronne HSSW-sourced water masses. The northern FIS drillhole moorings, however, can

517   be affected by circulation changes in Filchner Trough and thus were able to show the gradual

518   transition from Berkner-sourced ISW in early 2017 to the Ronne-sourced waters in early 2018

519   (H2021) that we observed in Filchner Trough during PS111.

Figure 11: Schematic representation of the regional circulation and its impact on the northern FIS edge during a) Berkner- and b) Ronne-modes. The top panels indicate a map view of the circulation, while the bottom panels represent a meridional cross-section of the FIS edge. The Berkner-mode is dominated by Berkner-HSSW in Filchner Trough, associated with enhanced melt rates at the northern base of FIS. The Ronne-mode features an enhanced circulation in the cavity with an enhanced outflow of ISW from underneath FIS. Basal melting is reduced at northern FIS, but is enhanced inside the cavity. Circulation arrows are based on insights gained from the 2018 CTD survey and drillhole moorings (H2021) as well as from earlier literature-based findings.

The transition to a greater dominance of sub-FRIS waters in Filchner Trough is also reflected in GBMW fractions. Based on measurements from the same drillholes as discussed above (Figure 1), Huhn et al. (2018) report neon-based GBMW baseline fractions of 1.0-3.6% directly at the FIS base, and lower fractions of <0.4% near the bottom of the northern FIS and in Filchner Trough in 2016. These values are consistent with the (stable oxygen isotopes-based) fractions of 0.4% in Filchner Trough in 2017 reported by Akhoudas et al. (2020). In 2018, the FIS front was dominated by ISW, coincident with the highest water mass age (Figure 9) and elevated GBMW fractions of 0.8-1.0% below a depth of 600 m. These fractions directly agree with the fractions measured by Huhn et al. (2018, see their Figure 3) at the northern FIS drillhole sites. Our observations overall indicate an intensified sub-ice shelf circulation, which led to a

540   flushing of older water masses from the FRIS cavity into Filchner Trough, characterized by

541   higher melt water fractions and low temperatures. This flushing was likely forced by a recent

542   intensification of sea ice formation and HSSW-production north of RIS (Figure 12), as will be

543   discussed in the following section.

544   The impact of varying circulation modes is most notable beneath the northern FIS and in

545   Filchner Trough. Stronger inflow of HSSW via Ronne Depression leads to enhanced input of

546   heat into the ice shelf cavity, which will be available for ice shelf melting and ISW production

547   underneath RIS. Furthermore, stronger inflow results in intensified outflow of ISW at the FIS

548   front, which limits melting at the northern FIS edge. Instead, freezing underneath the ice shelf

549   increases due to a combination of ascending ISW and a rise of the local freezing temperature

550   (Figure 11b). In contrast, in the absence of a significant northward flow out of FIS, Berkner-

551   HSSW circulation is strong enough to impact the FIS front and locally enhance ice shelf melting

552   (Figure 11a). This concept is supported by time series from two ApRES (autonomous phase-

553   sensitive Radio Echo Sounders), deployed at and near a drillhole on the northeastern FIS. Basal

554   melt rates there decreased from 1.3 m per year in 2017 to 0.8 m per year in 2018 (H2021).

555

556

557

559   **on a simulation with the Finite Element Sea ice Ocean Model (FESOM; Timmermann et al., 2012) forced**
560   **with data from the ERA-Interim reanalysis. The anomalies are shown relative to the mean sea ice production**
561   **of 116 km^3 year^{-1}.**

562

563   4.3 <u>Decadal variability of Ronne- and Berkner-sourced Ice Shelf Water in Filchner</u>

564   <u>Trough</u>

565   In contrast to the low interannual variability of the hydrographic structure along RIS, the

566   conditions off FIS are subject to greater variability impacted by local HSSW-production as well

567   as the strength of the sub-FRIS circulation and outflow. Historical data derived from expeditions

568   over more than four decades on the southern Weddell Sea continental shelf underline the

569   variability and shift between Ronne- and Berkner HSSW-sourced ISW in Filchner Trough, as

570   represented by near-bottom salinity in front of FIS (Figure 13). First, the ~0.5 psu higher initial

571   sea surface salinities in the southwest (Figure 2b) explain the more saline Ronne-HSSW

572   compared with Berkner-HSSW. Further, the bathymetry underneath FRIS guides Ronne-HSSW

573   far into the cavity and toward greater pressure, which increases the basal melt potential, resulting

574   in colder and fresher ISW. Berkner-HSSW, however, enters the shallower cavity west of Berkner

575   Island or flows directly into Filchner Trough, and therefore interacts with the ice base at

576   significantly shallower depths (Figure 11). This results in warmer and more saline ISW

577   compared with Ronne HSSW-sourced ISW (see H2021). The two modes are therefore

578   categorized by near-bottom salinities as measured in front of FIS of <34.65 (Ronne-mode, source

579   salinity >34.7) or >34.65 (Berkner-mode, source salinity <34.7) (Figure 13). The near-bottom

580   salinities in Filchner Trough from surveys across a 45-year time period indicate a considerable

581   spatial and interannual variability in near-bottom water properties, suggesting that water mass

582   characteristics alternated regularly between Ronne HSSW-derived ISW and Berkner-HSSW.

583   However, despite relatively clear differences in the source salinities characterizing Ronne- and

584   Berkner-modes, the densities vary only little and not consistently (not shown). For the stations

585   considered in the source salinity computations (encircled in Figure 13), the mean potential

586   density at depths below 600 m is 27.88 ± 0.13 kg m^{-3}, and varies less than 0.05 kg m^{-3} between

587   the different surveys. This small range of FIS front densities, independent of the prevailing

588   circulation mode, is still above the potential density of mWDW (~27.8 kg m^{-3}, Figure 8), which

589   suggests that alternating modes do not directly impact the mWDW inflow dynamics. However,

590   the bias in the available station distribution in the southern Filchner Trough limits the statistical

591   significance of this analysis.

592

593

594

603

604   A strong Ronne-dominance as observed in 2018 leads to outflowing ISW on the western
605 Filchner Trough slope, flushing the shelf in the Berkner-HSSW formation regions (Figure 3a and
606 11b). The formation of HSSW on Berkner Bank requires that surface waters reach the density of
607 the Ronne HSSW-sourced ISW to convectively mix the water column. Once denser, the
608 Berkner-HSSW will be able to spread and restrict the northward flow of Ronne-sourced ISW
609 underneath FIS. Radar-sensed basal melting near the FIS front is indeed enhanced when induced
610 by Berkner-HSSW (H2021), which produces ISW outflows that are less dense than the Ronne
611 HSSW-sourced ISW. Hence, without enhanced sea ice formation in the Ronne polynya, driving a
612 more vigorous cavity circulation, fresher FIS outflows would set up a feedback loop that
613 continuously reduces the density of the Berkner-HSSW. This would promote a transition to
614 fresher water masses in Filchner Trough with consequences for the processes at the continental
615 shelf break. The fact that ocean densities in the lower Filchner Trough remained remarkably

616   stable under shifting source water types in the past suggests that an oscillating dominance of the

617   two circulation modes may indeed be part of the internal variability that interacts with the

618   varying forcing of the system.

619   Sea ice production and the resulting salt fluxes in the southwestern Weddell Sea are the main

620   source for Ronne-HSSW, which is the driver of the circulation underneath FRIS. Sea ice

621   production primarily depends on air-sea heat fluxes, which are further controlled by winds, sea

622   ice concentration and water column structure. In particular, extended periods of southerly and

623   southwesterly winds lead to polynya events and, consequently, large sea ice formation rates. This

624   connection between large-scale atmospheric conditions and sea ice formation in the southwestern

625   Weddell Sea is further discussed by H2021, who found that a westward displacement of the

626   Amundsen Sea Low leads to enhanced southerly winds over RIS associated with positive phases

627   of the SAM (Southern Annular Mode). For instance, a positive SAM along with vast open water

628   areas in 1998 coincided with the highest sea ice production rates within the last three decades

629   (Figure 12; Nicholls and Østerhus, 2004; Haid and Timmermann, 2013). Sea ice production in

630   the southwest Weddell Sea showed a decreasing trend after 2006 (Figure 12) coincident with a

631   decreasing number of polynya days (Paul et al., 2015), which likely resulted in the lower

632   presence of Ronne HSSW-sourced ISW in Filchner Trough before 2017. Nevertheless, sea ice

633   production increased again thereafter with two positive anomalies in 2016 and 2017 in response

634   to a period of synoptically enhanced southerly winds (H2021), which then set up the conditions

635   observed in 2018.

636

637   **5) Summary and Conclusions**

638   This paper provides a 2018-status update on the hydrographic conditions along the entire

639   length of FRIS in the southern Weddell Sea, based on a tightly-spaced CTD and noble gas tracer

640   survey. The conditions found off RIS were similar to those previously described, including a

641   strong presence of HSSW in Ronne Depression, a core of outflowing ISW and an inflow of

642   mWDW from Central Trough (Nicholls et al., 2003). Filchner Trough, however, was strongly

643   dominated by ISW (temperature <-2.0°C) along the entire ice shelf front, with a well-defined

644   core of <-2.2°C-Ronne HSSW-sourced ISW, and only slightly warmer (-2.1°C) water below

645   ~700 m (Figure 6). The outflowing ISW core leans against the western flank of Filchner Trough

646   and is identifiable in both geostrophic velocities (Figure 5) and noble gas tracers (Figure 3d-e,

647   Figure 4, Figure 9). Anthropogenic trace gases were used to date water masses, and the

648   difference in water mass age between the source waters off both FIS and RIS provides insights

649   into the circulation time scales (Figure 9). These analyses indicate a two-year travel time from

650   Ronne Depression to the western slope of Filchner Trough at the FIS front, which agrees with

651   earlier estimates of the direct route around Berkner Island (Nicholls and Østerhus, 2004). A less

652   direct route through the deeper cavity must have been taken by those waters exiting via the

653   central and eastern Filchner Trough, indicated by water masses more than 6 years older than the

654   Ronne-HSSW source waters (Figure 9). Additional northern CTD transects (Figure 6 transects 2

655   and 3) show waters colder than -1.9°C in the entire Filchner Trough to the north, as well as north

656   of the sill below 400 m (Figure 6 transect 4). These observations exemplify the export of dense

657   FRIS-formed ISW across the sill to the Weddell Sea continental slope, widely known as a

658   precursor for AABW and thus important for the global overturning circulation. Based on noble

659   gas tracers, we found a maximum GBMW content of 1.0 % in the coldest ISW-core and 0.6-

660   0.9% in the remaining ISW along the FIS front. This was close to the fractions found a few years

661   earlier underneath FIS (Huhn et al., 2018) and not significantly different from those regions that

662   were also measured in 1995 (Figure 4). While Filchner Trough featured Berkner-derived water

663   mass characteristics in 2017 (Darelius and Sallée, 2018, Akhoudas et al., 2020), our 2018-survey

664   was dominated by Ronne-sourced properties, underlining the recent shift from Berkner- to

665   Ronne-mode (Figure 11) first identified by moorings underneath FIS in mid-2017 (H2021). This

666   shift follows two years of strong sea ice formation in the southwestern Weddell Sea (Figure 12)

667   and thus enhanced production of Ronne-HSSW, which fuels the circulation underneath FRIS and

668   impacts the ice shelf-ocean interaction in two ways. First, the shift changes the spatial

669   distribution of basal melting with lower rates near the FIS front and higher rates at greater depth

670   inside the cavity (Figure 11). Second, dense ISW production is promoted, which is important in

671   maintaining dense shelf waters that effectively block any larger-scale influence of mWDW. This

672   water mass of open ocean origin is generally present at the Filchner Sill and known to penetrate

673   southward along the eastern slope of Filchner Trough (Ryan et al., 2017).

674   The importance of HSSW and ISW as precursors for AABW broadens the importance of the

675   sea ice production and processes taking place underneath FRIS, as ~50% of the deep water

676   formed in the southern hemisphere originates from the Weddell Sea (Meredith, 2013). The

677   southern Weddell Sea receives fresher Eastern Shelf Water via the coastal current (Nicholls et

al., 2009), which contributes to the observed increasing sea surface salinity from 33.5 to 34.5 toward the southwest (Figure 2b) and the overall higher salinity and density of the Ronne-HSSW compared with HSSW formed on Berkner Bank. A strong Ronne-dominance as observed in 2018 leads to ISW outflow on the western Filchner Trough slope and also preconditions the ocean conditions in the Berkner-HSSW formation region (Figure 3). This recycling of ISW on the continental shelf suggests an internal feedback loop that would lead to a continuous freshening in Filchner Trough in the absence of dense water supply from Ronne Depression under a sustained Berkner-mode. Instead, the relatively stable density seen in historical data from Filchner Trough suggests that the regular alternations between Ronne HSSW-derived ISW and Berkner-HSSW may be part of the internal variability of the system. However, the sparse station coverage between the different surveys (Figure 13) limits our understanding of the relevant processes, formation mechanisms, and climatic importance of the Ronne-vs-Berkner-mode discussion.

Overall, the FRIS system is strongly controlled by sea ice production in the southern Weddell Sea, which depends on polynyas caused by off-shore winds advecting cold air from the Antarctic continent. The recent return to a Ronne-mode has been linked to anomalies in the synoptic circulation over and east of the Antarctic Peninsula (H2021). If these anomalies would continue to persist under climate change, a strengthening of the density barrier at the continental slope, maintaining low melt rates of FRIS, could be a possible response. However, HSSW-formation depends on surface forcing and on sea surface properties impacting stratification. For instance, local changes in sea ice formation or glacial melt distribution, as might be expected under continued warming (Timmermann and Hellmer, 2013; Hellmer et al., 2017), may negatively impact the dense water production on the southern Weddell Sea continental shelf and thus weaken the oceanic protection of FRIS. The global importance of the Antarctic Ice Sheet underlines the need for in-situ observations such as those collected during 2018 as well as from moorings on the shelf and underneath FRIS, complemented with autonomous platforms such as floats and gliders. Such detailed observations are necessary to monitor potential changes around FRIS and to advance the process understanding in order to improve numerical models and reduce their uncertainties in projecting future sea level rise.

Acknowledgments

709 Captain Schwarze and the crew of *RV Polarstern* for a very successful expedition. Andreas

710 Wisotzki carefully measured oxygen content from water samples during the expedition and

Figure captions

Figure 1: Map of the southern Weddell Sea including CTD stations from 2018 (black), 1995 (blue) and 1980 (red). Magenta stars indicate drillhole moorings mentioned in the text for reference (H2021). Ice Shelves are marked with cyan shading, bathymetry (Schaffer et al., 2016) is shown in blue color contours. The 500 m and 1000 m-isobaths are marked with black contours. Bathymetric and geographic features referred to in the text are indicated in the map. The area north of RIS inside the white line marks the region used to quantify sea ice production (Figure 12). The Filchner Trough framed by the yellow lines marks the inset used in Figure 6. The arrows indicate the inflow branches of modified Warm Deep Water (red) and the under-FRIS circulation fueled by the inflow of High Salinity Shelf Water (orange).

Figure 2: Along-track a) temperature (°C) and b) salinity measured by the ship's thermosalinograph at 11 m water depth, c) air temperature (°C), d) wind speed (m s-1) and e) direction (°T); f) sea level pressure (mbar) measured locally by RV Polarstern's weather system displayed against the day of February. Arrows indicating travel direction and occupation dates in panel a) are provided for better orientation. Cyan shading in a) and b) indicate ice sheets and ice shelves. Bathymetry contours in black mark every 500 m; the 1000 m-isobath is marked by the bold line.

Figure 3: Properties along the FRIS front in austral summer 2018: a) potential temperature (°C), b) salinity; c) oxygen (ml/l); d) SF6 (ppt), and e) CFC-12 (ppt). Station locations can be found in Figure 1 and are indicated by vertical black lines in panels a-c and by black dots in panels d-e. Objective mapping was used to interpolate between stations in panels d and e.

Figure 4: Glacial basal melt water fractions (%) along FRIS shown by colored dots at the sample location and depth in a) 2018 and b) 1995. Magenta contours in either panel marks the -2.0°C-isotherm as an indicator for ISW outflow based on the CTD transects in these years.

Figure 5: Geostrophic velocities referenced to 200 m (in cm s-1) along FRIS. Positive values indicate northward flow, i.e. into the page.

Figure 6: Filchner Trough CTD transects. The map is a zoom into the Filchner Trough region framed by the yellow box in the overview map in Figure 1 and shows the location of four transects. Stations are indicated by black dots on the map, highlighted by red lines. Bathymetry is displayed in color with 100 m-increments as shown by the colorbar. Potential temperature (left) and salinity (right) are shown for each transect. Station locations are indicated by vertical black lines. The number on each panel refers to the numbered transects in the map. Note that the panels are scaled according to degrees longitude for a better comparison. The seafloor bathymetry was drawn based on the depth of each CTD profile, which generally was sampled down to 5-10 m above the seafloor. Separate colormaps for temperature and salinity are displayed by the colorbars in the center of the Figure. Color ranges are identical for all 4 transects. Please note that maximum temperatures in transect 4 exceed the color-limit capped at -1.3 °C. For better readability, the small cross-areas featuring -1.0°C and -0.5°C waters are displayed in magenta and green contours, respectively.

994   <u>Figure 7</u>: Temperature-salinity-diagram from CTD stations in Filchner Trough, representing
995   water masses at and below surface freezing. Colors code the individual transects, shown in
996   Figure 6. The yellow circle highlights the near-bottom properties related to Berkner-HSSW. σ0–
997   contours from 27.55 to 27.9 kg m-3 are marked by gray contours, the surface freezing
998   temperature relative to salinity is shown by the black dashed line.
999
1000   <u>Figure 8</u>: a) Temperature-salinity-diagram from all CTD stations along FRIS, b) from Ronne
1001   (west of 50°W), and c) Filchner (east of 43°W) CTD stations from 1980 (red), 1995 (cyan) and
1002   2018 (black). Station locations are shown in Figure 1. σ0–contours are shown in black lines in
1003   0.1 kg m-3-increments. The dashed line indicates the surface freezing temperature. Yellow boxes
1004   in panel a) indicate the temperature-salinity-properties of panels b) and c).
1005
1006   <u>Figure 9</u>: Water mass age based on the SF6/CFC12-ratio (see data and methods section) along
1007   the FRIS front. The bathymetry is based on station depth inferred from CTD profiles. Data are
1008   interpolated between the data points (black dots) and displayed in 1 year-color contours. ISW
1009   outflows are marked with white arrows.
1010
1011   <u>Figure 10</u>: Temperature-salinity-diagram from CTD stations along FRIS. Colors differentiate
1012   between Ronne (blue), Berkner (red) and Filchner (green) stations. The blue star marks the mean
1013   temperature and salinity of ISW colder than -2.0°C including the standard deviations indicated
1014   by the vertical and horizontal lines. The Gade lines bound possible source water salinities
1015   (without considering mixing) at the intersection with the line of surface freezing points (black
1016   dashed line). The Gade lines neglect the effect of heat conduction into the ice and use a slope of
1017   2.4 K/psu.
1018
1019   <u>Figure 11</u>: Schematic representation of the regional circulation and its impact on the northern FIS
1020   edge during a) Berkner- and b) Ronne-modes. The top panels indicate a map view of the
1021   circulation, while the bottom panels represent a meridional cross-section of the FIS edge. The
1022   Berkner-mode is dominated by Berkner-HSSW in Filchner Trough, associated with enhanced
1023   melt rates at the northern base of FIS. The Ronne-mode features an enhanced circulation in the
1024   cavity with an enhanced outflow of ISW from underneath FIS. Basal melting is reduced at
1025   northern FIS, but is enhanced inside the cavity. Circulation arrows are based on insights gained
1026   from the 2018 CTD survey and drillhole moorings (H2021) as well as from earlier literature-
1027   based findings.
1028
1029   <u>Figure 12</u>: Sea ice production anomalies in the Ronne sector (white area in Figure 1) from 1985-
1030   2017 based on a simulation with the Finite Element Sea ice Ocean Model (FESOM;
1031   Timmermann et al., 2012) forced with data from the ERA-Interim reanalysis. The anomalies are
1032   shown relative to the mean sea ice production of 116 km3 year-1.
1033
1034   <u>Figure 13</u>: Maps of the Filchner region showing near-bottom salinity observed from CTD
1035   surveys since 1973. The magenta line encircles those profiles used for averaging the source
1036   water salinity of the ISW in front of Filchner Ice Shelf in order to identify the dominant
1037   circulation mode. Source salinities >34.70 and <34.70 indicate Ronne and Berkner-modes,
1038   respectively. Berkner ("B")- or Ronne("R")-mode conditions are marked by the respective letter
1039   in the upper left, the mean source salinity is provided below in each panel. A bold letter indicates

1040   that the mode is statistically significant within one standard deviation. A non-bold letter indicates
1041   statistical insignificance, i.e. too few data points or mean source salinities close to 34.70.
1042   Bathymetry (Schaffer et al., 2016) is displayed by black contours in 100 m-isobaths.
