Abstract

In an effort to reveal the subsurface hydraulic changes in fractures by seismic monitoring, aperture-related velocity changes need to be investigated. We developed a numerical approach for calculating changes in elastic wave velocity with fracture aperture opening by determining the internal energy of a digitized fracture model based on natural rough surfaces. The simulated local elastic energy revealed that the interaction energy converged within 1.5 mm of the mean fracture position, and was insignificant unless the fractures intersected. This energetic approach clarified the aperture–velocity relationship and reproduced the experimental results. Further calculations using digital fractures with various sizes and density demonstrated that the velocity can be accounted for by the superposition of a linear function of fracture density and quadratic function of aperture, and is insensitive to the fracture size. Although the relationship between fracture permeability and elastic wave velocity (i.e., the k–V relationship) depends on the fracture density, the offset-normalized k–V relationship shows clear linearity with the fracture density. The proposed k–V relationship as a function of the aperture and fracture density indicates that laboratory-scale fracture properties of a single fracture can be applied to multiple fractures on a larger scale. Our findings can be used to interpret temporal changes in seismic observations and to monitor fluid flow in fractures.

Plain Language Summary

A monitoring of seismic velocity will be useful to find changes in the permeability of fractures, if the relationship between elastic wave velocity and fracture aperture is known. This study presents a numerical approach to calculating changes in elastic wave velocity, based on the elastic energy calculated using a digital rock model having simulated natural fractures. The proposed approach revealed the relationship between fracture aperture and elastic wave velocities propagating through the fracture. Further calculations showed linear decreases of wave velocities with the number of fractured layers per unit thickness (i.e., the fracture density), whereas the velocities do not significantly change with fracture size. Our results will allow us to formulate the relationship between fracture permeability and elastic wave velocity as a function of fracture density. The proposed equation suggests that the properties of a single fracture on the laboratory scale can be used for a large-scale multiple fracture system. The results will provide a prospective application of seismic data to be used in the sustainable development of fractured reservoirs such as geothermal resources.

1. Introduction

Monitoring fracture systems is important in geology and geophysics, because fractures control mass and heat transport in the subsurface, which are linked to earthquakes (i.e., the fault valve model; Sibson et al., 1988) and fractured reservoir management (e.g., Manga et al., 2012). Recent advances in seismic monitoring techniques have revealed changes in elastic wave velocity associated with earthquakes (e.g., Brenguier et al., 2008; Nimiya et al., 2017) and geothermal fluid production (Sánchez-Pastor et al., 2019; Taira et al., 2018). These velocity changes in the vicinity of a fractured zone will reflect subsurface stress changes that also cause changes in the contact state of fractures (i.e., apertures or asperities). Numerous experimental and numerical studies of fractured rock masses have revealed that aperture networks are strongly related to hydraulic properties, whereas asperity contacts contribute to elastic properties (Guéguen & Boutéca, 2004; Guéguen & Palciauskas, 1994; Ishibashi et al., 2015; Nolte et al., 1989; Sawayama et al., 2021a). An aperture increase or contact area decrease triggered by a subsurface stress change will cause

68 both an increase in permeability and a decrease in elastic constants. Therefore, the hydraulic and
69 elastic properties may be related reflecting changes in the microstructures of the fractures (i.e.,
70 apertures and asperities). Previous studies have reported a correlation between permeability and
71 fracture specific stiffness, which is related to the amplitude of the seismic response (i.e.,
72 attenuation), but have not established a direct correlation between permeability and elastic wave
73 velocity (Pyrak-Nolte & Nolte, 2016; Wang & Cardenas, 2016). A direct correlation would be
74 beneficial for evaluating changes in subsurface fracture flow by seismic velocity monitoring.

75 The fracture permeability k is commonly described by the aperture d as $k = d^2/12$ in the
76 classical parallel plate model (e.g., Witherspoon et al., 1980). It can be linked to the elastic wave
77 velocity if the aperture–velocity relationship is known. However, no established model has
78 correlated these parameters. Although some experimental studies have reported a velocity increase
79 in fractured rock masses at elevated stress (e.g., Nara et al., 2011; Kurtuluş et al., 2012; Yang et
80 al., 2019), evaluating actual changes in the apertures is not feasible by experimental studies. As
81 such, it is important to study the elastic wave velocity of a fractured rock mass by numerical
82 simulations, while changing the aperture between two rough surfaces. A numerical approach
83 allows the S-wave velocity to be calculated even at lower stresses (i.e., a larger aperture), which
84 could then be used to interpret the velocity changes in the upper crust inferred from cross-
85 correlation of ambient noise (e.g., Brenguier et al., 2008; Ikeda & Tsuji, 2018; Nimiya et al., 2017;
86 Sánchez-Pastor et al., 2019; Taira et al., 2018).

87 To determine the aperture–velocity relationship of a fractured rock mass, this study
88 developed a numerical method that calculates anisotropic elastic constants (i.e., the stiffness tensor
89 C_{ijkl}) based on an internal energy calculation using the finite element method (FEM). The finite
90 element analysis of static elasticity has been used to determine the elastic wave velocity in digitized
91 rock images (e.g., Andrä et al., 2013; Sain et al., 2014). These conventional FEM approaches can
92 only calculate effective elastic constants in a purely isotropic case under isostrain conditions (i.e.,
93 the upper bound). The energetic approach makes it possible to calculate the stiffness tensor of
94 vertical transverse isotropic (VTI) media. We also implemented the constant stress assumption in
95 the numerical self-consistent scheme (Nishizawa, 1982) to mitigate the overestimation of elastic
96 constants using the conventional FEM approach. We first applied our approach to synthetic rough
97 fractures based on the natural rough surfaces in contact, and then undertook calculations with
98 aperture opening to estimate the changes in elastic wave velocity during deformation. The
99 calculations were extended to fractures with different sizes and densities. After the experimental
100 verification, we demonstrate that there is a possible correlation with fracture permeability, which
101 highlights an application of our approach.

2. Energy of fractured rock according to elasticity theory

103 The elastic field of a composite medium comprising a homogeneous matrix and inclusions
104 was described by Eshelby (1957). Let E_0 be the elastic energy of an intact material when it is free
105 of inhomogeneities and under certain surface loads which produce an internal stress field
106 corresponding to the surface stress $\sigma_{ij}{}^A$. In what follows, we consider the isothermal condition. If
107 we introduce inhomogeneity with keeping $\sigma_{ij}{}^A$ constant, the elastic energy is augmented by
108 $-E_{int}(\sigma_{ij}{}^A)$, which represents the interaction energy of the applied stress and the inhomogeneities
109 in the medium. If such a process is at constant load (i.e., isostress conditions), then the total energy
110 associated with inclusions is described by the Gibbs free energy G as:

111
$$G = \frac{1}{2} C_{ijkl}{}^{-1} \sigma_{ij}{}^{A} \sigma_{kl}{}^{A} = E_0 - E_{int}(\sigma_{ij}{}^{A}). \tag{1}$$

112 where C_{ijkl} is the stiffness tensor and $C_{ijkl}{}^{-1}$ is its inverse and termed the elastic compliance
113 tensor. The same elastic energy E_0 can be obtained as a function of the surface strain $\varepsilon_{ij}{}^{A}$,
114 corresponding to the surface displacements that are produced by the same surface loads. When the
115 inhomogeneities are introduced, the interaction energy is augmented by $E_{int}(\varepsilon_{ij}{}^{A})$, leading to the
116 Helmholtz free energy F:

117
$$F = \frac{1}{2} C_{ijkl} \varepsilon_{ij}{}^{A} \varepsilon_{kl}{}^{A} = E_0 + E_{int}(\varepsilon_{ij}{}^{A}). \tag{2}$$

118 Eshelby (1957) proposed an analytical solution for E_{int} using the eigen or stress-free strain $\varepsilon_{kl}{}^{T}$,
119 by assuming an elliptical inclusion that is often modeled as cracks (Nishizawa, 1982; Nishizawa
120 & Kanagawa, 2010; Yamamoto et al., 1981). However, the complex shapes of fracture apertures
121 cannot be modeled as cracks, and prevented us from analytically calculating E_{int}. We directly
122 calculated F as:

123
$$F = \frac{1}{2} \iiint_{V} \sigma_{ij}(x,y,z)\varepsilon_{ij}(x,y,z)dxdydz, \tag{3}$$

124 where V is the volume of the material, and $\sigma_{ij}(x,y,z)$ and $\varepsilon_{ij}(x,y,z)$ are the stress and strain at
125 a point (x, y, z) in the material. C_{ijkl} is defined as the second derivative of F:

126
$$C_{ijkl} = \frac{\partial^2 F}{\partial \varepsilon_{ij}{}^{A} \partial \varepsilon_{kl}{}^{A}}. \tag{4}$$

127   The conventional FEM calculation solves for the microscopic stress and strain according
128 to an arbitrarily input macroscopic strain $\varepsilon_{ij}{}^{A}$. We approximated F in the FEM by discretizing Eq.
129 (3). However, a constant value of $\varepsilon_{ij}{}^{A}$ will yield C_{ijkl} in the isostrain case (upper bound). To
130 incorporate the constant stress assumption into the conventional FEM, we adopted the numerical
131 self-consistent (NSC) scheme (Le Ravalec & Guéguen, 1996a, 1996b; Nishizawa & Kanagawa,
132 2010; Yamamoto et al., 1981). In this approach, $\varepsilon_{ij}{}^{A}$ was updated in a stepwise fashion to keep
133 the initially assumed macroscopic stress $\sigma_{ij}{}^{\text{ini}}$ constant with increasing mean aperture. The
134 iterative process is described as:

135
$$\varepsilon_{kl}{}^{A(n)} = C_{ijkl}^{(n-1)^{-1}} \sigma_{ij}{}^{\text{ini}}, \tag{5}$$

136 where the superscripts n or $(n-1)$ of $\varepsilon_{kl}{}^{A}$ and C_{ijkl}^{-1} denote the values of the nth or $(n-1)$th
137 step. This integrated approach using FEM and NSC methods enables us to solve reasonable
138 changes in the anisotropic form of C_{ijkl}, which is not feasible with a conventional FEM approach.
139 Given that a jointed rock can be assumed to be transversely isotropic along the z-axis (i.e.,
140 perpendicular to the fracture plane), the objective C_{ijkl} has a hexagonal symmetry (Mavko et al.,
141 2009):

142
$$C_{ijkl} = \begin{bmatrix} C_{1111} & C_{1122} & C_{1133} & 0 & 0 & 0 \\ C_{1122} & C_{1111} & C_{1133} & 0 & 0 & 0 \\ C_{1133} & C_{1133} & C_{3333} & 0 & 0 & 0 \\ 0 & 0 & 0 & C_{1212} & 0 & 0 \\ 0 & 0 & 0 & 0 & C_{1212} & 0 \\ 0 & 0 & 0 & 0 & 0 & \dfrac{C_{1111} - C_{1122}}{2} \end{bmatrix}.$$
(6)

3. Data and Method

144   3.1. Sample and digitization

145   We prepared digital models of a fractured rock mass from natural rough surfaces, which
146   were also used in Sawayama et al. (2021b) for calculating fracture permeability as a function of
147   the fracture aperture. The surface topography of a natural rock fracture was initially mapped using
148   a laser profilometer (Keyence, VR-3050) with a grid of cells 23.433 µm square. This raw data for
149   the natural rough surfaces were used to further validate our approach (Section 3.3). We then
150   analyzed the fractal characteristics of the natural rough surfaces, obtaining a fractal dimension $D =$
151   2.4, roughness $s = 0.49$, and mismatch length scale $\lambda_c = 0.57$ mm (see Sawayama et al., 2021b for
152   details of this analysis). Based on these values, we constructed a synthetic fracture that was 24 ×
153   24 mm in size with an isotropic surface topography by applying fractional Brownian motion
154   (Brown, 1995; Matsuki et al., 2006; Sawayama et al., 2021b). This method can reproduce a self-
155   similar fracture surface with the same amplitude and a different relative phase for each fracture
156   surface, where the matedness at wavelengths larger than λ_c and a mismatch at smaller wavelengths
157   were modeled. The obtained topographies of the hanging wall and footwall are shown in Fig. 1a
158   and b, respectively. A 3D fracture model was then created numerically by pairing these surfaces
159   (Fig. 1c). The aperture of the model was varied by uniformly reducing the local apertures (Fig. 1d
160   and e). Finally, we prepared 16 models that have different mean apertures ($d = 0.05$–0.2 mm) with
161   a grid size of 0.1 mm. Although the elastic properties calculated from the FEM are potentially
162   affected by the model grid size (Arns et al., 2002), the 0.1 mm grid size was confirmed to be
163   detailed enough for our approach (Text S1 and Fig. S1). The thickness of the base models is 10
164   mm, which provides 0.5%–2.0% of the porosity variation.

Figure 1. Topography maps of the (a) hanging wall and (b) footwall of the synthetic fracture. (c) Three-dimensional view of the digital fracture model. (d) Asperity distributions of digital fracture models having a different mean aperture.

3.2. Fracture upscaling and multiplication

It is well known that fracture roughness (i.e., the standard deviation of the surface height) increases with fracture length. This study incorporated this scaling law into our model as follows (Matuski et al., 2006):

$$s = s_0 \left(\frac{L}{L_0}\right)^{3-D}, \tag{7}$$

where s_0 is the standard deviation of the surface height along a linear profile of size L_0 on a fracture surface and s is the standard deviation of the surface height of an arbitrary fracture size L. In this study, we used $L_0 = 24$ mm and $s_0 = 0.49$ mm from our results for the natural rock fracture, and generated three different fracture sizes ($L = 24$, 48, and 96 mm). The reconstruction of the surface roughness of a fracture from an observed spectrum is a stochastic process, and thus we needed to examine stochastic fluctuations in the models created by different random seeds. This study used five different random seeds to validate the repeatability of our simulation results for each fracture size.

182   The multiple fracture models were constructed by assuming a vertical series of single
183   fractures having the same aperture value. We selected 1.5 mm as the distance between two single-
184   aligned fractures (i.e., the fracture spacing), because the interaction energy almost converged at
185   this distance. When the fracture spacing was smaller than this distance, the energy anomalies near
186   the fracture planes interfere with each other, resulting in a higher energy peak than the model with
187   a 3.0 mm fracture spacing (Fig. S2). We prepared up to five-layered fractures with 1.5 mm spacing
188   that were each 10 mm in thickness (i.e., fracture density $D_F = 1$–5 cm^{-1}).

189   3.3. Anisotropic elastic constants of fractured rock determined by finite-element analysis

190   Based on Eshelby's theory, an embedded transverse fracture (i.e., inclusion) in the model
191   (Fig. 1c) augments the internal energy (i.e., Helmholz free energy F), which is more significant as
192   the aperture opens. This study analyzed quasi-static changes in F by modifying the conventional
193   FEM approach (Arns et al., 2002; Garboczi, 1998; Sawayama et al., 2021a). In the analysis, we
194   imposed a periodic boundary in all directions, which simulates an infinitely large model with a
195   constant fracture density in a vertical direction (i.e., the number of fractures per unit thickness).
196   The base model has a single fracture in a 10 mm thick layer, and the fracture density $D_F = 1$ cm^{-1}.
197   The elastic constants we assigned in each solid and fluid node for the FEM are listed in Table 1,
198   based on P- and S-wave velocity (6.04 km/s and 3.33 km/s) under a high confining pressure.

199   The workflow of the modified FEM is shown in Fig. 2, which comprises three iteration
200   steps: the conjugate gradient, isostress, and NSC steps. The calculation begins with the smallest
201   aperture model ($d = 0.05$ mm). We first used a homogeneous $\varepsilon_{kl}{}^A$, where we assumed an isotropic
202   C_{ijkl} for the intact rock ($C_{1111} = C_{3333} = K_s + 4/3\,\mu_s$, $C_{1212} = (C_{1111} - C_{1122})/2 = \mu_s$, and
203    $C_{1122} = C_{1133} = K_s - 2/3\mu_s$, where K_s and μ_s are the bulk and shear moduli of the solid phase,
204   respectively) and $\sigma_{ij}{}^{\text{ini}} = 20$ MPa in Eq. (5). Although the actual stress–strain state is
205   heterogeneous due to the presence of the fracture, we first neglected the small error on the energy
206   calculation caused by this assumption for convenience. The local internal energy was calculated
207   by the FEM, which was repeated to minimize the gradient of F with respect to the displacement
208   by the conjugate gradient iteration (Fig. 2a). After the convergence, C_{ijkl} can be solved with Eq.
209   (4). We numerically differentiated F with respect to $\varepsilon_{ij}{}^A$ by assuming the vertical transverse
210   isotropy (VTI) of the fractured rock model. However, it should be noted that the actual stress state
211    $\sigma_{ij}{}^A$ differs from $\sigma_{ij}{}^{\text{ini}}$, because C_{ijkl} of the fractured rock model is more compliant than that of
212   the intact rock. Therefore, we updated $\varepsilon_{kl}{}^A$ using a calculated C_{ijkl} (VTI) with Eq. (5) to satisfy
213    $\sigma_{ij}{}^{\text{ini}} = 20$MPa, and then repeated the calculation. The calculation was iterated until $\sigma_{ij}{}^A$ became
214   close enough to $\sigma_{ij}{}^{\text{ini}}$ (Fig. 2b). This isostress iteration process converged within the third iteration
215   (Fig. S3). The final result for C_{ijkl} was then used for determining the initial input strain of the
216   proceeding model. Similarly, we proceeded with the calculations towards the largest aperture
217   model ($d = 0.2$ mm) by updating the input strain $\varepsilon_{ij}{}^A$ in each fracture aperture model such that
218    $\sigma_{ij}{}^A = \sigma_{ij}{}^{\text{ini}} = 20$ MPa (Fig. 2c). This NSC process enabled us to simulate the isostress condition
219   and minimize the gap between the two bounds obtained from the isostress and isostrain conditions,
220   thereby providing reasonable changes in the stiffness tensors (Yamamoto et al., 1981).

228 **Figure 2.** Flow diagram of the approach used for calculating the stiffness tensor by integrating the
229 finite element and numerical self-consistent methods. The input strain for the finite element model
230 was consecutively updated until the macroscopic stress became close to 20 MPa at each aperture
231 condition.

3.4. Experimental verification

We verified the numerical results for the elastic wave velocity using experimental results. The experimental sample was prepared as a cylindrical specimen (35 mm in diameter and 70 mm long), in which the fracture plane was parallel to the central axis. After mapping the fracture surfaces as described in Section 3.1, the sample was restored to its original state. The P-wave velocity in the direction normal to the fracture plane was then measured by the pulse transmission method at eight effective normal stresses from P_{eff} = 1–15 MPa. The input trigger of a pulse was set to a frequency of 250 kHz and amplitude of 10 Vp-p. Details of the experimental setup were described in Sawayama et al. (2018a).

The simulated velocity change of the experimental fracture was evaluated with our modified FEM approach. The aperture between the two surfaces in the digital model was adjusted such that the model had a simulated permeability equivalent to that measured in the experiments at each stress state (Sawayama et al., 2021b). The thickness was determined by matching with the measured fracture porosity in this sample (1.6% at atmospheric pressure; Sawayama et al., 2021b). The wavelength under our experimental conditions is at least ten times larger than the largest length of the estimated aperture (0.06 mm). It should also be noted that the experimental velocity change includes both velocity changes in the matrix and fracture associated with the elevated stress. Therefore, we modeled the changes in elastic constants in a matrix (K_m and μ_m) based on P- and S-wave velocities at elevated P_{eff} as K_m = 0.128 P_{eff} + 6.49 and μ_m = 0.0048 P_{eff} + 27.29, based on an experiment on an intact andesite sample retrieved from the same borehole as the fractured sample.

4. Results

4.1. Elastic energy

Based on the 24 × 24 mm synthetic fracture, we calculated local distributions of stress, strain, and elastic energy with the FEM. Figure 3 shows the cross-sections of their local distributions with a 0.2 mm mean aperture. The vertical stress and strain (σ_{33} and ε_{33}) are normalized by their macroscopic values ($\sigma_{33}{}^A$ and $\varepsilon_{33}{}^A$), whereas the local energy is normalized by the energy of the intact rock (E_0). The mean position of the fracture plane is located at the center of the model (5 mm in the *z*-direction). The stress and energy are mainly concentrated on the edges of the fracture asperity contacts (Fig. 3a), whereas the strain is accumulated inside the fracture (Fig. 3b). Notably, their anomalies converge near the fracture. Figure 4 shows the horizontal mean energy and corresponding cross-sections of the energy distributions. The peak of the energy is consistent with the mean fracture position. It is clearly evident that the energy is only localized at 3.5–6.5 mm in the vertical position (i.e., 1.5 mm from the mean fracture position). The energy anomaly disappears near the top (z = 1.0 mm) and bottom (z = 9.0 mm) of the model, indicating the model thickness was sufficiently large at the given aperture conditions.
Figure 3. Local distribution of normalized values of the (a) vertical stress, (b) vertical strain, and (c) elastic energy of the 24×24 mm fractures at a 0.2 mm mean aperture.

Figure 4. (a) Areal average of the elastic energy in the *x*–*y*-plane and (b) areal distribution of local elastic energy at 0.2 mm mean aperture.

276   The change in the elastic energy of the base model shows a non-linear increase with
277 aperture opening (Fig. S4). Note that the energy change obtained with our approach was slightly
278 larger than the result without updating the strain input, and this discrepancy became more
279 significant as the aperture increased (Fig. S4a). Consequently, the conventional approach (i.e., the
280 isostrain assumption) underestimated the velocity change due to the fracture aperture opening (Fig.
281 S4b). In addition to the aperture change, the model thickness potentially affects the elastic energy.
282 When the model thickness is larger, the energy anomaly near the fracture will be relatively smaller.
283 We therefore analyzed the elastic energy when the thickness was twice that of the base model (i.e.,
284 20 mm thickness). The relative energy changes of the 20-mm-thick model were smaller than those
285 of the base model (Fig. S4c). Given that we adopted a periodic boundary in all directions, twice
286 the model thickness is equivalent to half of the fracture density D_F (i.e., number of fractures per
287 unit thickness). When two single-aligned fractures were embedded in the 20 mm thickness (i.e.,
288 the same D_F as the base model), both results showed good agreement (Fig. S4c).

289 4.2. Velocity changes with aperture opening

290   From the stiffness tensor determined from the elastic energy, P-wave velocity V_p and S-
291 wave velocity V_s in the direction normal to the fracture plane were calculated as:

292
$$V_p = \sqrt{\frac{C_{3333}}{\rho}}, \qquad V_s = \sqrt{\frac{C_{1212}}{\rho}}, \tag{8}$$

293 where ρ is the arithmetic average of densities of solid and pore water (Table 1). The resultant
294 changes with aperture opening are plotted in Fig. 5 (a), and show the non-linear decrease of V_p and
295 V_s. The change in V_s is slightly smaller than that of V_p, which is consistent with the numerical
296 simulation and laboratory experiments on natural rock fractures (Cha et al., 2009; Sawayama et
297 al., 2021a).

298   The phase velocities of the following three modes were also evaluated. The velocities of
299 quasi-longitudinal (qP), quasi-shear (qS), and pure shear (SH) modes in transversely isotropic
300 material along the *z*-axis are given as (Mavko et al., 2009):

301
$$V_{qP}(\theta) = \sqrt{\frac{C_{1111}\sin^2\theta + C_{3333}\cos^2\theta + C_{1212} + \sqrt{M(\theta)}}{2\rho}}, \tag{9}$$

302
$$V_{qS}(\theta) = \sqrt{\frac{C_{1111}\sin^2\theta + C_{3333}\cos^2\theta + C_{1212} - \sqrt{M(\theta)}}{2\rho}}, \tag{10}$$

303
$$V_{SH}(\theta) = \sqrt{\frac{(C_{1111} - C_{1122})\sin^2\theta + 2C_{1212}\cos^2\theta}{2\rho}}, \tag{11}$$

304 where

305
$$M(\theta) = [(C_{1111} - C_{1212})\sin^2\theta - (C_{3333} - C_{1212})\cos^2\theta]^2 + (C_{1133} + C_{1212})^2\sin^2\theta. \tag{12}$$

306 θ is the angle between the wave vector and symmetry axis ($\theta = 0$ for a propagation direction
307 normal to the fracture plane), indicating $V_{qP}(0) = V_p$ and $V_{qS}(0) = V_{SH}(0) = V_s$ in Eq. (8). The

308 results are shown in Fig. 5b and c. The aperture effect on the velocity change is significant at $\theta <$
309 70˚ (Fig. 5b). V_{qS} and V_{SH} show different trends, whereby V_{qS} is mostly faster than V_{SH}, but slower
310 than V_{SH} at $\theta > 70˚$. This discrepancy between the two modes of S-waves reflects the angular
311 dependence on shear wave anisotropy, which can be expressed as $(V_{qS} - V_{SH})/[(V_{qS} + V_{SH})/2]$
312 (Fig. 5d). Consequently, the anisotropy shows a peak at $\theta = 40˚$, and the peak value increases with
313 aperture opening. The peak angle has a similar value to that of a shale fracture, which will be <45˚
314 depending on the anisotropy of the material (Berryman, 2008).

315

316
317 **Figure 5.** Plots showing the (a) P- and S-wave velocity in a direction perpendicular to the fracture
318 plane as a function of the mean aperture, (b) angular phase velocity distributions for *qP* at 0.05
319 and 0.2 mm mean aperture, (c) angular phase velocity distributions for *qS* and *SH* waves, and (d)
320 shear wave anisotropy as a function of the angle under various aperture conditions.

321   4.3. Fracture upscaling

322   We extended the calculations to different sizes of synthetic fractures (24, 48, and 96 mm)
323   with five different random seeds. Figure 6 shows changes in V_p, V_s, and shear wave anisotropy
324   versus the mean aperture at various fracture sizes and random seeds. These plots show there are
325   no significant differences resulting from changes in the random seeds and fracture size,
326   demonstrating both the repeatability of the simulations and the size-independent characteristics of
327   the velocities in the simulated fractures. These size-independent characteristics suggest that
328   fracture size does not strongly affect the velocity perturbation when the wavelength is much larger
329   than the fracture.

330
331   **Figure 6.** Changes in the (a) P-wave velocity, (b) S-wave velocity, and (c) shear wave anisotropy
332   as functions of the mean aperture. Symbol shapes correspond to the different random seeds, and
333   their colors correspond to the different fracture sizes. θ is the angle between the wave vector and
334   symmetry axis ($\theta = 0$ for a propagation direction perpendicular to the fracture plane).

13

335   4.4. Fracture density

336   Figure 7 shows changes in V_p, V_s, and shear wave anisotropy versus the mean aperture in a
337   multi-fracture system. V_p and V_s clearly decrease with an increasing number of fractures, and this
338   effect is prominent in larger aperture models (Fig. 7a and b). Shear wave anisotropy also shows a
339   similar trend (Fig. 7c). Although we used a model having a 1.5 mm fracture spacing, the effect of
340   the fracture spacing on V_p, V_s, and shear wave anisotropy was small (Fig. S5a–c). This is because
341   the elastic energy was less sensitive to the fracture spacing, unless the fractures intersected (Fig.
342   S5d). The same D_F model shows the same velocity and anisotropy trends regardless of the different
343   model thicknesses (Fig. S6). These results indicate that the experimentally determined
344   dependencies on both the number of fractures and rock thickness (e.g., Kurtuluş et al., 2012; Yang
345   et al., 2019) are accounted for by considering the fracture density.

346
347   **Figure 7.** Changes in the (a) P-wave velocity, (b) S-wave velocity, and (c) shear wave anisotropy
348   at an angle $\theta = 45°$ as a function of the mean aperture. The symbol colors correspond to the
349   different fracture densities.

350   4.5. Comparison of numerical and experimental results

351   The P-wave velocities obtained from our numerical approach were compared with
352   experimental data. Figure 8 shows the P-wave velocities in the experiment and from the numerical
353   approach. The raw data indicate that the numerical results for the digital rock models of all fracture
354   areas have a slightly lower velocity than the experimental values. This may be due to the mismatch
355   between the numerical model and actual path area in the experimental setup, as the point-source
356   input pulse in the experiment will have a smaller scope than the entire fracture plane. When the
357   ray path is approximately straight, the propagating wave interacts with the medium inside a prolate
358   spheroid, with a major axis that links the source and receiver transducers, which is known as the
359   first Fresnel zone. The length of the minor axis of the spheroid r is given by (Spetzler & Snieder,
360   2004):

$$r = \sqrt{\frac{l\lambda}{2}}. \tag{13}$$

362   where l and λ are the half-distance between the source and receiver transducers and the wavelength
363   of the propagating P-wave, respectively. The experimental pulse frequency of 250 kHz yields $r =$
364   13.3 mm by assuming $V_p = 5$ km/s. We therefore constructed the digital rock model using 13.3 mm
365   square-sized fracture from the experimental source position to undertake a further simulation. The
366   updated simulation result is more like the experimental value (FZ in Fig. 8). A small discrepancy
367   may arise from the gap between the estimated porosity or asperity contacts, based on the
368   permeability, and actual values, as the velocity is more sensitive to these factors than the
369   permeability (Sawayama et al., 2021a). Overall, the trends of the experimental results are
370   consistent with the simulated velocity by incorporating the matrix velocity change and model
371   fracture size according to the experimental ray path.

372

Figure 8. Experimental and simulated P-wave velocity with increasing effective normal stress.
Solid and open symbols represent experimental and simulated results, respectively. The raw and
FZ simulation data are the P-wave velocity of the entire fracture plane and estimated first Fresnel
zone, respectively.

378   **5. Discussion and applications**

379   We have demonstrated that the changes in elastic energy (and therefore the elastic wave
380   velocity) of the fracture in Eshelby's model can be accounted for by the fracture aperture and
381   density (Figs 5 and 7), which the volume fraction of an inclusion represents. The velocity in the
382   direction normal to the fracture can be simply modeled as a horizontal layered structure comprising
383   matrix and an inclusion. Assuming a long-wavelength limit, V_p is given by the effective medium
384   theory (Mavko et al., 2009):

385
$$V_p = \sqrt{\frac{M}{\rho}}. \tag{14}$$

386   Given that the fracture is filled with pore water, the effective P-wave modulus M $(K + 4/3\mu)$ is
387   obtained from the Backus average:

388
$$\frac{1}{M} = \frac{1 - f_w}{M_s} + \frac{f_w}{M_w}, \tag{15}$$

389   where f_w is the volume fraction of pore water given by the ratio of the mean aperture to model
390   thickness, and M_s and M_w are the P-wave modulus of the solid and pore water, respectively. The
391   predicted V_p from Eq. (14) of our digital fracture at a mean aperture $d = 0.2$ mm yields 4.44 km/s,
392   which is much smaller than the simulation result (Fig. 7a). Moreover, the simulation results show
393   that the velocity at $d = 0.2$ mm and $D_F = 1$ cm^{-1} is much smaller than the velocity at $d = 0.1$ mm
394   and $D_F = 2$ cm^{-1} (Fig. 7a), even though Eq. (14) yields the same V_p. In both cases, the simple
395   effective medium theory will underestimate the velocity, indicating that f_w cannot account for the
396   velocity change of mated fractures. As such, both the mean aperture and fracture density are
397   essential for predicting the velocity of mated fractures. We therefore modeled the velocity changes
398   as functions of aperture and fracture density. Figure 9 shows V_p and V_s normalized by the matrix
399   velocity ($V_p{}^o = 6.04$ km/s; $V_s{}^o = 3.33$ km/s) as functions of aperture and fracture density. The
400   colored surface in Fig. 9 represents the curve fitting results using the following models:

401
$$\frac{V_p}{V_p{}^o} = 1 - D_F(1.39d^2 - 0.136d + 5.90 \times 10^{-3}), \tag{16}$$

402
$$\frac{V_s}{V_s{}^o} = 1 - D_F(0.952d^2 - 0.0277d + 2.98 \times 10^{-3}). \tag{17}$$

403   The empirical model predictions are consistent with our simulation results in the base model (Fig.
404   9), and with a much wider range of D_F values for the 20 mm thickness model (Fig. S6). These
405   empirical models imply that the elastic wave velocity of the fractured rock mass can be accounted
406   for by the superposition of a linear function of the fracture density and quadratic function of the
407   aperture. A linear decrease in elastic wave velocity with fracture density has also been reported in
408   some experimental studies (Kahraman, 2001; Kurtuluş et al., 2012; Yang et al., 2019). These
409   studies observed different trends for the relationship depending on the rock samples, which might
410   be related to the fracture characteristics (e.g., roughness, fractal dimensions, and mismatch length
411   scale). These characteristics may also affect aperture-related velocity changes in a single mated
412   fracture (Cha et al., 2009; Mohd-Nordin, 2016; Sawayama et al., 2021a). Future studies need to

413 clarify the mechanism of determining the empirical parameters with respect to fracture geometry.
414 Notably, the proposed empirical model allows us to extrapolate the aperture–velocity relationship
415 for a single fracture to multiple fractures comprising a vertical series of the same fractal surfaces.
416

417
418 **Figure 9** Curve fitting results of the (a) P-wave velocity and (b) S-wave velocity normalized to
419 the matrix values. The plots show the simulation results and the color surfaces represent the curve
420 fitting model based on Eqs (16) and (17).

421

422   One application of our finding is that it is possible to correlate the elastic wave velocity
423 with fracture permeability with respect to the aperture and fracture density. When the number of
424 fractured layers N_F having the same mean aperture d is vertically accumulated in a unit volume,
425 the total fracture permeability k can be simply given by $k = (N_F d)^2/12$, while the elastic wave
426 velocities can be derived from the empirical models (Eqs (16) and (17)). The predicted relationship
427 between fracture permeability and elastic wave velocity (i.e., the k–V relationship) is shown in Fig.
428 10. The simulation results for the permeability (Sawayama et al., 2021b) and elastic wave
429 velocities (Fig. 9) using the same digital fracture models are also plotted, and are consistent with
430 the predictions and show no significant changes with fracture size. Both the V_p and V_s changes are
431 larger at higher permeability ($\log(k) < 10.8$ at $N_F=1$), whereas they are almost constant at lower
432 permeability. This reflects the different mechanisms underlying both properties; the velocity
433 change becomes small after a large fraction of the asperities become in contact, while permeability
434 continuously decreases with increasing contact area (Sawayama et al., 2021a). Fracture density
435 changes the k–V relationship, and changes in velocity and permeability at higher D_F are much
436 larger than those at lower D_F. This suggests that the direct prediction of permeability from the
437 observed velocity might be difficult in a natural setting, unless D_F is known.
Figure 10. Plots of the fracture permeability versus (a) P-wave velocity and (b) S-wave velocity. The plots show the simulation results and the symbol shapes represent different fracture length sizes. The colored lines show the predicted relationships of different fracture densities extrapolated from the results of the single fracture model.

In contrast, the offset of the k–V relationship can be neglected by focusing on the relative changes in these properties for monitoring. The k–V relationship is thus normalized by the reference values. We used $d = 0.065$ mm as the reference value, where the dominant flow channel is disconnected (Sawayama et al., 2021b). Consequently, the relative k–V relationship shows clear linearity in linear coordinates, and the trend depends on fracture density (Fig. 11). Therefore, the k–V relationship can be modeled as follows:

$$\frac{k}{k'} = \frac{\alpha_p}{D_F}\frac{V_p' - V_p}{V_p'}, \tag{18}$$

$$\frac{k}{k'} = \frac{\alpha_s}{D_F}\frac{V_s' - V_s}{V_s'}, \tag{19}$$

where k', V_p', and V_s' are arbitrary reference values of the permeability, and P- and S-wave velocities, respectively. The empirical parameters α_p and α_s represent the linearity of the k–V_p and k–V_s relationships for a single fracture, respectively. The predicted lines using $\alpha_p = 3000$ and $\alpha_s = 2500$ are also shown in Fig. 11. The predicted k–V_p relationship is consistent with the simulation results for $k/k' < 30$ (Fig. 11a), whereas the trend deviates from the simulation results at $k/k' > 30$. This deviation point corresponds to $d = 0.13$ mm (or ~25% of the contact area), suggesting that changes in V_p become small when the fracture contact is weaker than this threshold. This trend for $k/k' > 30$ shows good agreement when $\alpha_p = 2200$ (Fig. 11a). Although no studies have correlated the fracture permeability and velocity, some experimental studies (e.g., Alam et al., 2011; Prasad, 2003) have found that the trend of the k–V_p relationship for a porous rock varies with the lithology, which may be due to pore and grain features (e.g., tortuosity, specific surface area, impurities, and clay contents). Our results revealed that the trend of the k–V_p relationship for a fracture is strongly related to D_F, and will also change according to the fracture contact state. In contrast, the trend of

465   the k–V_s relationship is irrelative to the contact state, and constant in fractures with the same fractal
466   characteristics and D_F (Fig. 11b). Although the empirical parameter α can vary with fracture types,
467   it can be determined from the k–V relationship for a single fracture. This finding implies that
468   investigations of small-scale single fractures and the k–V relationship can be extrapolated to
469   multiple fractures in natural settings. Therefore, velocity monitoring (especially V_s) can potentially
470   evaluate changes in fracture permeability.

471

472
473   **Figure 11.** Plots of permeability versus (a) P-wave velocity and (b) S-wave velocity normalized
474   to the reference values (see the text for details). The symbol colors represent the fracture densities
475   and the lines denote the predicted relationships based on Eqs (18) and (19).

476

477   Although the presented digital rock models are mated fractures based on isotropic surfaces,
478   it should be noted that permeability enhancement by hydraulic stimulation is triggered not only by
479   joint openings but also by shear slip (e.g., Rinaldi & Rutqvist, 2019). Future work should extend
480   this approach to solving for the stiffness tensor in the orthorhombic case (e.g., sheared fractures)
481   to confirm the limitations of the proposed formulae. Another limitation of the formulae arises from
482   the assumption that there is no matrix velocity change. It is known that the velocity change at
483   elevated pressure is significant at higher crack density (i.e., lower stress), but is smaller at lower
484   crack density (i.e., higher stress). Such a pressure effect on velocity change will be smaller if cracks
485   are filled with water and have low aspect ratios (Nur & Simmons, 1969; O'Connnell & Budiansky,
486   1974; Hadley, 1976; Meglis et al., 1996; Paterson & Wang, 2005; Watanabe & Higuchi, 2015).
487   Therefore, the proposed empirical model could be used for rocks with a low crack aspect ratio
488   (e.g., volcanic rocks) or under higher crustal stress conditions, which has negligibly small changes
489   in matrix velocity. Given that our approach can incorporate matrix velocity changes when
490   experimental data are available (Fig. 8), our method can be extended to rocks with a high crack
491   aspect ratio (e.g., granite). Moreover, the method needs to be tested further for size dependencies,
492   because the studied experimental fracture was much smaller than natural fractures. For example,
493   a test site of the enhanced geothermal system has a kilometer-scale fracture (e.g., Didana et al.,
494   2017). Although our study adopted a zero frequency assumption for the velocity calculation, the
495   scaling effect on velocity can be addressed by considering the ratio of the finite wavelengths and
496   fracture size (Mavko et al., 2009). Because finite-difference time-domain modeling of wave fields

497 in fractured media requires more complex assumptions, such as fracture compliance (Bakulin et
498 al., 2000; Minato & Ghose, 2016; Pyrak-Nolte et al., 1990), future studies need to further
499 investigate the scale dependency of velocity using this technique.

4. Conclusions

501 We developed a method for calculating the hexagonal form of the stiffness tensor based on internal
502 energy calculations, and investigated the changes in elastic wave velocities and shear wave
503 anisotropy with aperture opening. Simulated local elastic energy revealed that the interaction
504 energy converged within 1.5 mm of the mean fracture position, and was insignificant unless the
505 fractures intersected. The energetic approach integrating FEM and NSC methods identified the
506 aperture–velocity relationship and reproduced the experimental results. Further calculations using
507 digital fractures with various sizes and densities showed that the elastic wave velocity can be
508 accounted for by the superposition of a linear function of the fracture density and quadratic
509 function of the aperture, and is independent of the fracture size. We also showed that the k–V
510 relationship is independent of fracture size, but dependent on fracture density. In contrast, the k–V
511 relationship shows a clear linearity with fracture density when the offset is normalized by arbitrary
512 reference values. Although further study is needed to confirm the empirical parameters
513 determining the slope of this relationship, our results indicate that laboratory-scale fracture
514 properties for a single fracture can be extended to multiple fractures. Our findings indicate that
515 temporal changes in seismic properties might be used for monitoring fracture flow.
