Key Points

(1) Whether the apparent enhancement corresponds to a true enhancement in electron density.

(2) Following the dispersion relation of ion acoustic waves, two observations are analyzed.

(3) The apparent enhancement was falsified.

Plain Description

Above the reflection altitude of the high-frequency pump wave, an apparent electron density enhancement was observed during two ionospheric heating experiments conducted on 18 Oct. 2012 and 11 Mar. 2014 respectively. Those observations seem to be in conflict with the understanding that the high-frequency pump wave should be reflected at the reflection altitude, so that the ionosphere plasma should not be modified above the reflection altitude of the high-frequency pump wave. One needs to verify the validity of this enhancement. No significant modifications were found in the electron temperature and ion line frequency, post the comparison of the enhanced ion line and the background ion line. According to the dispersion of ion acoustic waves, this implies that no change occurred in the effective ion mass. Furthermore, the incident radiation and the drift velocity did not indicate a significant change in the ion species and their densities. Thus, the electron density did not truly change over the wide altitude range.

45 **Abstract**

46 During the course of ionospheric heating experiments, an apparent electron
47 density enhancement was observed at the European Incoherent Scatter Scientific
48 Association (EISCAT). The enhancement extended over a wide range of altitudes,
49 above the reflection altitude of the high-frequency pump wave. However, it remains
50 open whether this enhancement actually corresponds to a true enhancement in
51 electron density. Following the dispersion relation of ion acoustic waves, the
52 frequency ratio of the enhanced ion line to the background ion line suggests that the
53 profile of the effective ion mass might remain unchanged. Furthermore, the solar
54 radio flux and ion drift velocity indicated no significant changes in the ion species and
55 their densities. In conclusion, the electron density enhancement observed at EISCAT,
56 might not in fact be a true enhancement.

57 **1. Introduction**

58 In the F region of the ionosphere (altitudes >160 km), powerful high-frequency
59 (HF) pump waves can regularly induce an appreciable change in electron density in
60 the vicinity of the HF pump wave reflection altitude. Some typical studies in the past
61 have observed/theorised such electron density modifications. *Utlaut* and *Violette*
62 [1972] inferred a $\sim 7\%$ decrease in the electron density from ionograms recorded at the
63 Platteville Atmospheric Observatory, Colorado, USA (henceforth referred to as
64 Platteville). Later, using the typical parameters at the Arecibo Observatory, Puerto
65 Rico (henceforth referred to as Arecibo) and Platteville, *Meltz et al.* [1974] suggested
66 a theoretical decrease of $\sim 3\%$ in electron density, two minutes post the onset of HF
67 pumping. Experiments by *Djuth et al.* [1987] at Arecibo demonstrated that a decrease
68 of $\sim 10\text{--}15\%$ in the electron density was accompanied by a $1000\text{--}2000$ K increase in
69 the electron temperature. *Duncan et al.* [1988] reported the first thermally driven
70 decrease of $\sim 50\%$ in electron density. However, the observations at the European
71 Incoherent Scatter Scientific Association (EISCAT) showed both an increase and
72 decrease in the electron density in the vicinity of the reflection altitude of the HF

73 pump wave, demonstrating disagreements with a time-dependent numerical model
74 [Stocker *et al.*, 1992]. At the High Frequency Active Auroral Research Program
75 (HAARP), Pedersen *et al.* [2010, 2011] observed a large enhancement in electron
76 density at the altitude of ~ 220 km induced by the HF pump wave near the 2nd
77 electron gyroharmonic.

78 In recent years, an apparent enhancement in the electron density, induced by HF
79 pump waves in X mode [Senior *et al.*, 2013] and O mode [Wu *et al.*, 2016, 2017], was
80 observed over a wide range of altitudes above the pump wave reflection altitude.
81 Senior *et al.* [2013] found that the shape of the enhanced ion line corresponded very
82 closely with that of the ion line taken before the onset of pumping at the altitude of
83 ~ 300 km, and that the frequency of the plasma line showed no appreciable change at
84 the altitudes of ~ 321 km and ~ 339 km. It was concluded that the apparent
85 enhancement did not in fact correspond to a true enhancement in electron density.
86 Instead, it corresponded to the enhanced ion line by some unknown mechanisms,
87 which preferentially scatters the radar wave back along the magnetic field line.
88 Rietveld *et al.* [2020] proposed that medium and large-scale field-aligned irregularities
89 could refract the radar wave along the magnetic field. This may cause a strong radar
90 backscatter, appearing in the observation as an enhanced electron density. However,
91 Blagoveshchenskaya *et al.* [2022] claimed that this apparent enhancement did
92 correspond to a true enhancement in electron density and might be due to an increased
93 ionization resulting from the flux of accelerated electrons. It was expected that the
94 duct of the enhanced electron density may guide the HF pump wave along the
95 magnetic field line. Indeed, the debate continues over the apparent or true nature of
96 this enhancement in the electron density, and the conclusive proofs are still expected.

97 It is essential to confirm the apparent or true nature of the ionospheric electron
98 density enhancement, on which the research path of physical mechanisms heavily
99 depends. That is, if the apparent enhancement does in fact correspond to a true
100 enhancement in electron density, the research of physical mechanisms will focus on
101 the interaction between the HF pump wave and the ionospheric plasma, otherwise it
102 should focus on the scattering process of radar wave.

103 In this paper, an alternative method, confirming the apparent or true nature of the
104 ionospheric electron density enhancement, is presented, and two ionospheric heating
105 experiments are examined.

106 **2. Experiment and Data**

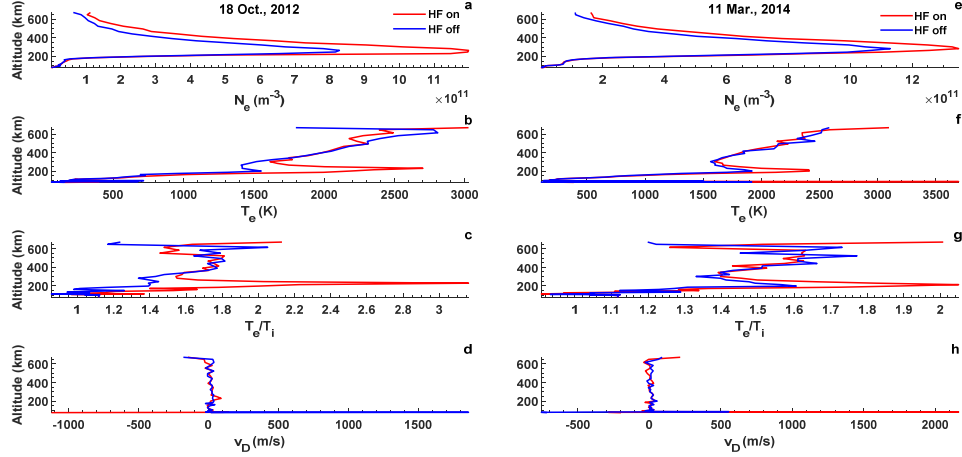

107 At EISCAT, near Tromsø, Norway (69.58°N, 19.21°E), the heating facility can
108 radiate an O / X mode HF pump wave in the frequency range of 4.0–8.0 MHz
109 [Rietveld *et al.*, 1993]. It also hosts an ultra-high frequency (UHF) incoherent scatter
110 radar (ISR), operating at 930.0 MHz [Rishbeth and van Eyken, 1993]. In this study, we
111 examined two experiments involving the aforementioned heating facility and UHF
112 ISR:

113 1) The first experiment (henceforth referred to as Experiment 1) was conducted by
114 Senior *et al.* [2013] on 18 October 2012, between 13:10–14:50 universal time (UT).
115 The heating facility was operated at 7.953 MHz, pointing in the field-aligned direction
116 (12° with the zenith, 186° with the azimuth), and with an effective radiated power
117 (ERP) of ~840.0 MW. The HF pump wave was modulated to stay on for 300 s,
118 followed by a break of 300 s, with the polarization switching between the O and X
119 modes on successive pulses, making an overall cycle of 1200 s. The radar beam began
120 in the field-aligned direction for the first 120 s, followed by an alignment of 11° and
121 13° with the zenith for 60 s each. Finally, the radar beam was returned to the
122 field-aligned direction for 60 s before turning off the HF pumping. The radar power
123 was measured at ~1.5 MW, with the HF pumping on, and at ~1.6 MW, after turning it
124 off.

125 2) The second experiment (henceforth referred to as Experiment 2) was conducted
126 by Wu *et al.* [2016, 2017] on 11 March 2014, between 12:30–14:30 UT. The heating
127 facility was operated at frequencies in steps of 2.8 kHz, starting from 6.7 MHz to 7.0
128 MHz. The ERP had a range of 56.0–78.0 MW. The O mode HF pump wave was
129 modulated to stay on for 18 min, and then, off for 12 min. The radar beam and HF
130 pump beam stayed in the field-aligned direction throughout the experiment. The radar

131 power was measured at ~ 1.4 MW, with the pumping on, and at ~ 1.5 MW after turning
 132 it off.

133 In addition, *Senior et al.* [2013] and *Wu et al.* [2016, 2017] gave a detailed
 134 description of the two experiments, in which more experimental information is
 135 available. To allow ion line smoothing, the ISR data was analyzed using an integration
 136 time of 60 s in this study.

137 **Figure 1.** (a) Mean electron density; (b) mean electron temperature; (c) mean ratio of electron
 138 temperature to ion temperature; and (d) mean ion drift velocity measured in Experiment 1. Each
 139 enhanced (red) / background (blue) value is the mean of the integration of the X-mode pump wave,
 140 over the final 60 s of the on/ off period, for five cycles. Subplots (e), (f), (g), and (h) correspond to (a),
 141 (b), (c), and (d), respectively, for Experiment 2. The description follows in Experiment 1, but measured
 142 only over three on/ off cycles. The values were obtained using Grand Unified Incoherent Scatter
 143 Design and Analysis Package (GUIDAP) [*Lehtinen and Huuskonen, 1996*].
 144

145 Figure 1 displays the mean electron density N_e , mean electron temperature T_e ,
 146 mean ratio of electron temperature to ion temperature $\frac{T_e}{T_i}$, and mean ion drift velocity

147 v_D . It can be seen that with the HF pumping on, N_e , T_e and $\frac{T_e}{T_i}$ increase

148 significantly in the narrow altitude range of ~ 200 – 300 km. This was attributed to (i)
 149 the weak leakage of the X mode pump wave into the O mode by *Senior et al.* [2013],
 150 and (ii) the HF enhanced ion line and upper hybrid resonance close to the reflection
 151 altitude of the HF pump wave by [*Wu et al., 2017*]. However, there exists no evidence
 152 of a significant change in v_D , i.e., the drift of ionosphere plasma was not active in the

geomagnetic field-aligned direction. In both cases, an unexpected enhancement of
 $\sim 20\text{--}50\%$ was observed in N_e above ~ 300 km, till the altitude limit of the radar
 measurement. This was consistent with the clear enhancement in the ion lines within
 the altitude range of $\sim 245\text{--}486$ km, as illustrated in Figure 2.

Figure 2. (a) Examples of ion lines measured in Experiment 1; (b) Examples of ion lines measured in Experiment 2. The ion lines were obtained using the EISCAT Real Time Graphic (RTG) package. The ion lines above the altitude of ~ 500 km were not shown due to the smaller signal to noise ratio (SNR) of the ISR echo. Additionally, the ion line measurement follows the same method as that in Figure 1.

Figure 2 illustrates examples of ion lines in the altitude range of $\sim 245\text{--}500$ km for both experiments. It is evident that in both cases, when the pumping is on, the ion lines at ~ 9.5 kHz are significantly enhanced in intensity. Based on the standard analysis of incoherent scatter, this observation indicates that the profile of electron density N_e should be modified by the HF pumping. Moreover, the intensity of the ion lines, below the altitude of ~ 314 km, are an order of magnitude more intensive than that above the altitude of ~ 314 km, i.e., depending on the N_e profile and the radar echo scattered from the scattering volume.

To summarize, as observed in Figures 1 and 2, an interesting enhancement is seen in N_e and the ion lines in the altitude range of $\sim 300\text{--}500$ km, when the HF pumping is on.

3. Discussion

174 It is assumed that the ionosphere plasma remains Maxwellian during the
 175 ionospheric heating experiments, and the GUIDAP and the RTG are valid for the
 176 ionosphere plasma illuminated by the HF pump. The assumption is based on four
 177 factors, namely, (i) the HF pump wave should be reflected at its reflection altitude
 178 [Robinson, 1989], and the ionosphere plasma should not be disturbed by the HF pump
 179 and should remain Maxwellian; (ii) only N_e was enhanced, whereas other
 180 parameters remained unchanged; (iii) if the apparent enhancement does not in fact
 181 correspond to a true enhancement in electron density, the ionosphere plasma should
 182 indeed remain Maxwellian; and (iiii) the parameters and ion lines in section (2) were
 183 obtained using the GUIDAP and the RTG, which are based on the standard
 184 incoherent scatter analysis.

185 For $\frac{T_e}{T_i} \leq 4$, the incoherent backscattered power P_r can be expressed as [Evans,
 186 1969; Djuth *et al.*, 1987; Duncan *et al.*, 1988]

$$187 \quad P_r \propto N_e \sigma_e \left(1 + \frac{T_e}{T_i} \right)^{-1}, \quad (1)$$

188 where σ_e is the Thomson cross section for electrons. In Figures 1(c) and 1(g), $\frac{T_e}{T_i}$
 189 shows no appreciable change in the altitude range of ~ 300 – 500 km in either
 190 experiment, implying that the ion lines in Fig. 2 were enhanced only as a result of the
 191 enhanced N_e , as indicated by Equation (1). On the other hand, N_e is enhanced
 192 solely because of the enhanced ion line, as indicated by the standard analysis of
 193 incoherent scatter. Thus, the enhanced N_e is equivalent to the enhanced ion line, that
 194 is, there is a closed relationship between the enhanced N_e and the enhanced ion line,
 195 which satisfies the incoherent scatter theory. Obviously, for confirming the apparent
 196 or true nature of the enhanced N_e , examining ion line intensity gets invalid. Hence,
 197 instead of ion line intensity, we will examine ion line frequency.

198 For the quasi-neutral F region of the ionosphere, an ion acoustic wave should

199 satisfy [Robinson, 1989; Kohl et al., 1993; Alcaydé, 1995]

200
$$\omega_i^2 = K_B \frac{\gamma T_i + T_e}{M_i} k_i^2, \quad (2)$$

201 where ω_i , k_i , γ , K_B , and M_i denote the angular frequency, wave number,
202 adiabatic index, Boltzmann constant, and effective ion mass, respectively. In the case
203 of backscatter, the ISR can only observe an ion acoustic wave satisfying the Bragg
204 condition $k_i = 2k_r$, where k_r denotes the wave number of ISR, and has a value of
205 19.5 m^{-1} for the UHF ISR at EISCAT. This implies that all the ion lines, observed in
206 Experiments 1 and 2 (Figure 2), satisfy the Bragg condition. In other words,
207 $k_i = 39 \text{ m}^{-1}$ is a constant for all examined ion lines, although those ion acoustic
208 waves within a small range of $2k_r$ may also contribute [Hagfors, 2003]. Moreover,
209 in both the experiments, the profiles of T_e and $\frac{T_e}{T_i}$ are independent of the HF
210 pumping in the altitude range of $\sim 300\text{--}500 \text{ km}$ (Figures 2(b), 2(c), 2(f) and 2(g)), i.e.,
211 although there exist some natural variability in T_e and $\frac{T_e}{T_i}$, they can still be
212 considered to have a quasi-constant profile in the altitude range of interest. Thus, the
213 straightforward relation between ω_i and M_i is obtained as

214
$$\omega_i^2 = \frac{\alpha}{M_i}, \quad (3)$$

215 where $\alpha = \left(\frac{\gamma}{T_e/T_i} + 1 \right) K_B T_e k_i^2$ is a quasi-constant profile in the altitude range of
216 interest.

Figure 3. (a) Ratio of the enhanced ion line frequency to the background ion line frequency, measured in Experiment 1; (b) Same ratio as in (a) for Experiment 2, where the frequency is the value corresponding to the maximum intensity of the right shoulder of the ion line.

Equation (3) indicates that, throughout the experiments, the profile of ω_i is dependent on that of M_i , namely, the change in ω_i should be dependent on the change in M_i . Figure 3 demonstrates the ratio of the enhanced ion line angular frequency ω_i^{on} to the background ion line angular frequency ω_i^{off} as a function of the altitude. Note that the SNR of this ratio in Experiment 1 is obviously larger than that in Experiment 2 (Figure 3). This may be the result of (i) the higher number of observation cycles in Experiment 1 (five cycles) over Experiment 2 (three cycles); and the higher radar power, with pumping on, in Experiment 1 than Experiment 2, i.e., the radar echo may have been more intense during Experiment 1.

From Figure 3(a), we can observe that $\frac{\omega_i^{\text{on}}}{\omega_i^{\text{off}}}$ has a mean of ~ 1.03 in the altitude range of $\sim 270\text{--}450$ km, implying that the ion line frequency was not significantly changed by the HF pumping in Experiment 1. Thus, following Equation (3), $\frac{M_i^{\text{off}}}{M_i^{\text{on}}}$ has a mean of ~ 1.06 in the altitude range of $\sim 270\text{--}450$ km, where M_i^{on} denote the effective ion mass with the pumping on, and M_i^{off} denote the effective ion mass with the pumping off. This implies that M_i was not significantly changed by the HF

236 pumping in the altitude range of $\sim 270\text{--}450$ km. However, below the altitude of ~ 270
 237 km, $\frac{\omega_i^{\text{on}}}{\omega_i^{\text{off}}}$ has a mean of ~ 1.2 . This change could be attributed to the natural ion
 238 acoustic waves close to ω_i^{on} . Here, for distinguishing from the high-frequency
 239 enhanced ion acoustic waves by the parametric decay instability, the natural ion
 240 acoustic waves denote the waves unaffected by the HF pump wave. The natural ion
 241 acoustic wave covers a wide frequency spectrum due to the highly varied ion mass
 242 distribution in the ionosphere, with some of the higher frequencies satisfying the
 243 Bragg condition, as T_e enhances in the scattering volume below the altitude of ~ 270
 244 km. In other words, following Equation (2) and considering a constant M_i , when T_e
 245 becomes higher in the scattering volume, the ion acoustic waves at the higher
 246 frequencies will be observed, so that $\frac{\omega_i^{\text{on}}}{\omega_i^{\text{off}}} > 1$ below the altitude of ~ 270 km; for
 247 instance, at the altitude of ~ 230 km, $\frac{T_e^{\text{on}}}{T_e^{\text{off}}} \approx 2.27$ in Figures 1(b) and $\frac{\omega_i^{\text{on}}}{\omega_i^{\text{off}}} \approx 1.50$ in
 248 Figures 3(a), where T_e^{on} denotes the electron temperature with the pumping on and
 249 T_e^{off} denotes the electron temperature with the pumping off. The measurement error,
 250 resulting from the small SNR, may lead to the increased frequency ratio mean value
 251 of ~ 1.24 above the altitude of ~ 450 km. Indeed, Equation (1) indicates that P_r must
 252 reduce above the altitude of ~ 450 km due to the decreasing N_e and increasing $\frac{T_e}{T_i}$,
 253 as shown in Figure 1. Similarly, the above behavior holds true for Experiment 2,
 254 namely, $\frac{\omega_i^{\text{on}}}{\omega_i^{\text{off}}}$ has a mean of ~ 1.04 in the altitude range of $\sim 270\text{--}450$ km, ~ 1.05
 255 below the altitude of ~ 270 km and ~ 1.4 above the altitude of ~ 450 km, as shown in
 256 Figure 3(b). It is important to note that in the altitude range of $\sim 270\text{--}450$ km, although
 257 the intensity of the ion lines is enhanced when the HF pumping is on, their frequency

remains unchanged. This implies that the M_i profile may remain unchanged in the altitude range of ~270–450 km.

Now, M_i can be expressed as

$$M_i = \frac{1}{N_e} \sum_i N_i m_i, \quad (4)$$

where N_i and m_i denote the density and mass of ion species, respectively. The quantity $N_i m_i$ is dependent on the incident radiation and the atmospheric composition, regardless of the corpuscular ionization which may be significant in the nighttime ionosphere [Rishbeth and Owen, 1969]. With a constant profile of atmospheric composition, a strong incident radiation could lead to an increase in N_i . As the indices of solar activity [Nicolet and Bossy, 1985], solar radio fluxes (SRFs) were measured at 245.0, 410.0, 610.0, 1415.0, 2695.0, 4995.0, 8800.0, and 15400.0 MHz, as shown in Figure 4. With the exception at 610.0 MHz, the SRFs do not demonstrate a significant and systematic variation in intensity during either experiment. At 610.0 MHz, the intensity of the SRF varied between ~10000–140000 solar flux units (SFU) in Experiment 1 and Experiment 2. Obviously, the SRFs do not temporally synchronize with the enhanced N_e . Also, the HF pump wave was reflected at the altitude of ~240 km and ~230 km for Experiments 1 and 2, respectively. Thus, in both experiments, it is reasonable to assume that the incident radiation does not have a significant impact on N_i .

Moreover, an analysis of the vertical drift of plasma, in both experiments shows that $v_D \approx 0$, indicating no active drift of plasma along the magnetic field lines, suggesting no induced change in the ion species. Nevertheless, a further examination of the change in ion species should be necessary. The ionosphere is mainly composed of hydrogen ion H^+ , helium ion He^+ , nitrogen ion N^+ , atomic oxygen ion O^+ , molecular oxygen ion O_2^+ and nitric oxide ion NO^+ in the altitude range of interest

283 [Robinson, 1989]. The frequency of the ion acoustic wave corresponding to H^+ is
 284 $\frac{k_r}{2\pi} \sqrt{\gamma \frac{K_B T_e}{m_{iH^+}}} \approx 43.7 \text{ kHz}$, where $k_r = 39 \text{ m}^{-1}$ for the UHF radar, γ denotes adiabatic
 285 index, K_B denotes Boltzmann constant, m_{iH^+} denotes mass of H^+ , T_e is $\sim 2000 \text{ K}$
 286 as given in **Figure (1)**. This indicates that the frequency of the ion acoustic wave
 287 corresponding to H^+ does not lie in the ion line channel of $[-40\text{kHz}, 40\text{kHz}]$ of UHF
 288 ISR at EISCAT, implying that the ion acoustic wave corresponding to H^+ cannot be
 289 collected by the UHF ISR. Similarly, the frequency of the ion acoustic wave
 290 corresponding to H_e^+ is $\sim 22 \text{ kHz}$, which significantly deviate from $\sim 9.5 \text{ kHz}$ shown
 291 in **Figure 2**. The frequencies of the ion acoustic waves corresponding to N^+ , O^+ ,
 292 O_2^+ and NO^+ , respectively, are $\sim 11.5 \text{ kHz}$, $\sim 10.5 \text{ kHz}$, $\sim 7.8 \text{ kHz}$ and $\sim 8 \text{ kHz}$, all of
 293 which may contribute to the ion lines at $\sim 9.5 \text{ kHz}$ shown in **Figure 2**. Considering
 294 that the frequencies of ion lines have no significant change in **Figure 2**, the ion
 295 species of N^+ , O^+ , O_2^+ and NO^+ may not have been modified in the altitude
 296 range of interest. Both these analyses strongly imply no modification has occurred in
 297 the ion species.

298 As a result, a straightforward relation between M_i and N_e can be obtained as,

$$299 \quad M_i = \frac{\beta}{N_e}, \quad (5)$$

300 where $\beta = \sum_i N_i m_i$ is a quasi-constant profile. Equation (5) indicates that, during the
 301 course of both experiments, since no modifications occurred in M_i , N_e must also
 302 not have been enhanced by the HF pumping in the altitude range of $\sim 270\text{--}450 \text{ km}$.

Figure 4. SRF above baseline as recorded at the Radio Solar Telescope Network radio observatory in San Vito, Italy. The abscissa origin denotes 13:00:00 UT on 18 October 2012 (Experiment 1) and 12:20:00 UT on 11 March 2014 (Experiment 2).

4. Summary

With regard to the apparent enhancement in electron density over a wide altitude range during the ionospheric heating experiments, the observations at EISCAT are investigated by following the dispersion relation of ion acoustic waves.

Our investigation showed no significant modifications in the ion line frequency and the electron temperature in the altitude range of interest, strongly implying that the profile of the effective ion mass must remain unchanged. Moreover, the incident radiation and the ion drift velocity indicate that the ion species and their densities must not have been modified. With the assumption of quasi-neutrality, it can be reasonably concluded that the apparent electron density enhancement does not in fact correspond to a true enhancement in electron density.

Acknowledgments

The authors thank the editor and the anonymous reviewers for their constructive and helpful comments, UK colleagues for their significant efforts in the experiment, National Centers for Environmental Information for providing the SRF data, and Dr. Ingemar Haggstrom for the fruitful discussion about EISCAT data. EISCAT is an international association supported by research organizations in China (CRIRP),

324 Finland (SA), Japan (NIPR and STEL), Norway (NFR), Sweden (VR), and the United
325 Kingdom (NERC). Dr. Xu is supported by the Taishan Scholars Project of Shandong
326 Province under Grant ts20190968.
