Key Points:

- Both rotational and linear solar wind magnetic holes can cross the bow shock
- At least some isolated magnetic holes in the magnetosheath are created in the solar wind
- Some magnetic holes fulfill the Rankine-Hugoniot jump conditions. No holes studied here show signs of a more complicated interaction with the bow shock

Abstract

Solar wind magnetic holes are localized depressions of the magnetic field strength, on time scales of seconds to minutes. We use Cluster multipoint measurements to identify 26 magnetic holes which are observed just upstream of the bow shock and, a short time later, downstream in the magnetosheath, thus showing that they can penetrate the bow shock and enter the magnetosheath. For two magnetic holes we show that the relation between upstream and downstream properties of the magnetic holes are well described by the MHD Rankine-Hugoniot jump conditions. We also present a small statistic investigation of the correlation between upstream and downstream observations of some properties of the magnetic holes. The temporal scale size, and magnetic field rotation across the magnetic holes are very similar for the upstream and downstream observations, while the depth of the magnetic holes varies more. The results are consistent with the interpretation that magnetic holes in Earth's and Mercury's magnetosheath are of solar wind origin, as has earlier been suggested. Since the solar wind magnetic holes can enter the magnetosheath, they may also interact with the magnetopause, representing a new type of localised solar wind-magnetosphere interaction.

1 Introduction

Solar wind magnetic holes are localized depressions in the magnetic field strength, on time scales of seconds or minutes. First observed by Turner et al. (1977) at 1 AU, they have since been observed in large parts of the heliosphere (Burlaga et al., 2007; Fränz et al., 2000; Karlsson et al., 2021; Madanian et al., 2019; Sperveslage et al., 2000; Tsurutani, Dasgupta, et al., 2002; Volwerk et al., 2020; Winterhalter et al., 1994; Yu et al., 2021; Zhang, Russell, Baumjohann, et al., 2008; Zhang et al., 2009). Already Turner et al. (1977) noted that magnetic holes could be classified according to how much the magnetic field vector rotated while the magnetic hole crossed the spacecraft. Magnetic holes with little change in the field direction were called 'linear' holes, while those with a considerable rotation were later called 'rotational' magnetic holes by Winterhalter et al. (1994). The two types of magnetic holes probably have different generation mechanisms, but there is no agreement on what those generation mechanisms are. For the rotational magnetic holes, flux annihilation due to (slow) reconnection at the current sheet associated with the magnetic field rotation has been suggested (Turner et al., 1977; Zhang, Russell, Zambelli, et al., 2008). For the linear magnetic holes, several generation mechanisms have been suggested. They may be remnants of magnetic mirror mode structures (e.g. Sperveslage et al., 2000; Winterhalter et al., 1994) or mirror mode structures created when the plasma is marginally mirror unstable (Karlsson et al., 2021). Other theories are that the magnetic holes are the result of non-linear interaction of Alfvén waves with the solar wind plasma (Buti et al., 2001; Tsurutani, Dasgupta, et al., 2002; Tsurutani, Galvan, et al., 2002), emerging coherent structures in solar wind turbulence (Perrone et al., 2016; Roytershteyn et al., 2015), or diamagnetic structures formed in the solar corona (Parkhomov et al., 2019).

While isolated magnetic holes in the solar wind have received considerable attention, similar structures in planetary magnetosheaths have not been investigated as much. Karlsson et al. (2015) studied localized density enhancements in Earth's magnetosheath, and observed that one class of such structures were associated with clear magnetic field decreases. They called such structures 'diamagnetic plasmoids' and suggested that they were actually solar wind magnetic holes that had crossed the bow shock. Similar structures were also found in the Mercury magnetosheath (Karlsson et al., 2016). The increase in density associated with the magnetic field decrease is consistent with the fact that linear solar wind magnetic holes have been showed to be pressure balance structures(e.g. Stevens & Kasper, 2007), where the magnetic field decrease is balanced by an increase in either density or temperature (Volwerk et al., 2020). Magnetic holes observed in the

66 inner coma of comet 67P were also interpreted to be of solar wind origin, and also showed
67 a density increase within the magnetic holes (Plaschke, Karlsson, et al., 2018)

68   The hypothesis that magnetosheath magnetic holes are of solar wind origin has some
69 further support. Recently Karlsson et al. (2021) made a comprehensive study of mag-
70 netic holes in the magnetosheath of Mercury and compared them to solar wind magnetic
71 holes near the planet. They found that the statistical distributions of temporal scale sizes,
72 magnetic field rotation across the holes, and depth of the magnetic holes were very sim-
73 ilar for the two populations, and suggested that the magnetosheath magnetic holes were
74 of solar wind origin also for Mercury (Karlsson et al., 2012; Karlsson et al., 2016). Fi-
75 nally, Parkhomov et al. (2019) reported on a structure observed in the solar wind that
76 shows considerable similarities to a magnetosheath diamagnetic plasmoid from the ob-
77 servations of Karlsson et al. (2015), with the solar wind observations made about 90 s
78 earlier then the magnetosheath one.

79   While the above hypothesis may seem reasonable, still solid observational proof is
80 missing, and an alternative hypothesis is that the magnetosheath magnetic holes are cre-
81 ated locally, downstream of the bow shock. Since magnetic mirror mode waves are known
82 to be excited in the magnetosheath at times of large ion temperature anisotropy, this would
83 be possible if magnetic hole generation is related to the mirror mode instability in some
84 way, as described above.

85   The purpose of this paper is to use Cluster multipoint measurements made simul-
86 taneously in the solar wind and the downstream magnetosheath to identify individual
87 magnetic holes observed by both the upstream and downstream spacecraft, and thus un-
88 equivocally show that at least some magnetosheath magnetic holes have a solar wind ori-
89 gin. We first discuss the data and methodology used, and then show a number of exam-
90 ples followed by some statistical properties of the full sample of magnetic holes, before
91 ending with a discussion and conclusions.

2 Data and Method

93   We use data from the FluxGate Magnetometer (FGM) and Cluster Ion Spectrom-
94 eter (CIS) instruments onboard the four Cluster spacecraft (Balogh et al., 2001; Réme
95 et al., 1997). We have manually identified time periods where at least one spacecraft is
96 located in the solar wind, while at the same time at least one other spacecraft is located
97 in the magnetosheath. The identification of solar wind or magnetosheath plasma is done
98 by inspection of the ion energy flux spectrograms, and ion velocity moments for the space-
99 craft where these are available, in combination with inspection of the magnetic field strength.
100 This is typically enough to make an unambiguous determination of the type of region
101 the spacecraft are located in, and the location of the bow shock.

102   We show an example of such a time interval from 2013-01-14 in Figure 1. Start-
103 ing with S/C 4, where both magnetic field and ion data are available, we can identify
104 two clear bow shock crossings (marked with 'BS', and dashed red lines) at around 10:46:50
105 UTC, and 10:52:40 UTC. In between these times we can see a typical solar wind (SW)
106 ion beam, and a low magnetic field strength of around 4 nT. At later times, and before
107 around 10:40 UTC we can observe the typical heated magnetosheath ion populations,
108 and a compressed magnetic field of around 13-14 nT. During this time the magnetic field
109 has a relatively low level of variability, and a high-energy ion population is not present.
110 This is consistent with the magnetosheath located behind a quasi-perpendicular bow shock,
111 as discussed by Karlsson et al. [2021b] (this paper is still in review///). Between 10:41
112 and 10:42:30 UTC, a region of enhanced magnetic field variability and higher-energy ions
113 can be seen. This is consistent with the convection of magnetic field variations and high-
114 energy particles associated with the foreshock ('FS', here indicating the magnetosheath
115 downstream of the foreshock) of the quasi-parallel bow shock being convected downstream
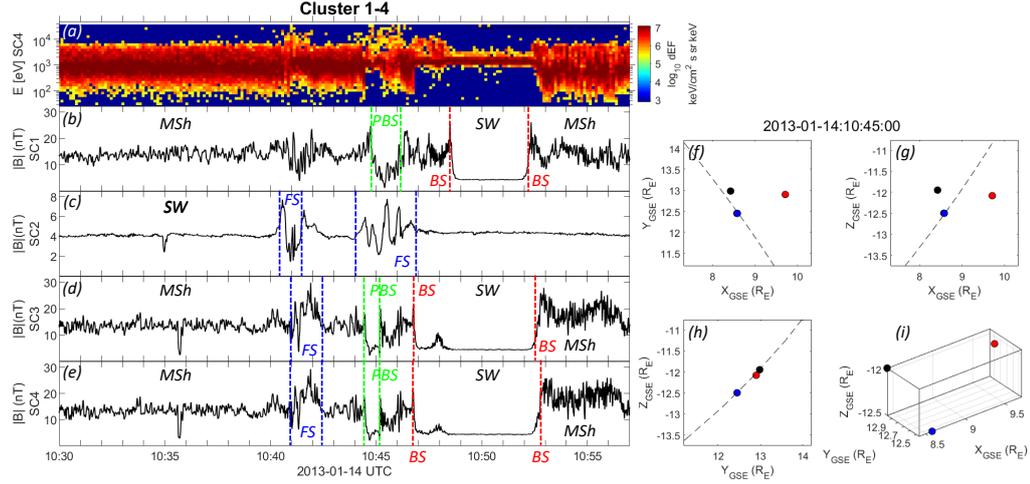

1.pdf

Figure 1. Panel (a): Differential ion flux, S/C 4, panels (b)-(e): magnetic field strength for S/C 1-4. Identified regions are marked with SW (solar wind), MSh (magnetosheath), BS (bow shock), FS (foreshock, and magnetosheath downstream of the foreshock), PBS (partial bow shock), see text for further details. Panels (f)-(i): spacecraft positions in various GSE coordinate projections. The spacecraft are identified by the standard Cluster color code; S/C 1 - black, S/C 2 - red, S/C 3 - green, S/4 - blue. S/C 3 and 4 are so close that they cannot be separated on the scale of these plots.

into the magnetosheath, again consistent with the results of Karlsson et al. [2021b]. Just
before 10:45 UTC the ion flux data indicates a small, partial excursion into the solar wind,
consistent with the decrease in magnetic field strength. We have marked this region 'PBS',
for 'partial bow shock crossing'. A similar decrease in magnetic field strength in S/C 3
and 4 has been marked in the same way. In the right part of Figure 1 is shown the space-
craft positions in GSE coordinates in four different projections at 10:45 UTC. Also in-
dicated is a model bow shock, determined by fitting a paraboloidal model (Merka et al.,
2003), using the bow shock position observed by S/C at the crossing taking place at around
10:46:50 UTC. The same method was also used in [Karlsson et al. 2021b].

For S/C 2, we see that the magnetic field strength during the whole interval shown
is comparable to that observed by S/C 4 when it is located in the solar wind. The mag-
netic field variability is also very low during almost the whole interval. We therefore con-
clude that S/C 2 is located in the solar wind during the whole interval, which is also con-
sistent with the spacecraft position relative to the model bow shock. The time intervals
marked with blue dashed lines are associated with some variations in the magnetic field
strength, which are likely associated with a foreshock region. This is also consistent with
the presence of a high-energy ion population in the downstream magnetosheath during
these times. This type of magnetosheath signatures downstream of the foreshock was
studied by Karlsson et al. [2021b]///. We have also estimated the angle θ_{Bn} between
the normal of the model bow shock (determined at the point where the solar wind in-
tersects the bow shock, assuming its velocity is purely in the GSE x direction) and the
magnetic field. θ_{Bn} is greater than $60°$ for the whole interval shown, except during the
time intervals marked by the blue lines, where it dips down to values below $45°$, consis-

139 tent with the interpretation that these variations are foreshock transients. In summary,
140 we conclude that S/C 2 is located in the solar wind during the whole interval shown.

141   S/C 3 is located very close to S/C 4 (it is therefore overplotted in the S/C loca-
142 tion plots), and the magnetic field variation are almost identical to those of S/C 4, mean-
143 ing that our interpretation of the location of S/C 3 with respect to the bow shock is the
144 same as that for S/C 4. The magnetic field variations of S/C 1 are also very similar, al-
145 though some differences can be seen due to the slightly larger separation from S/C 4.
146 Still, the general conclusions regarding the S/C 1 position relative to the magnetosheath
147 and solar wind regions remains similar to S/C 4.

148   This example shows how it is possible to unambiguously identify the position of
149 the spacecraft relative to the bow shock, and determine whether they are located in the
150 magnetosheath or the solar wind. For our search we concentrate on regions similar to
151 that shown in the beginning of the interval, between 10:30 and 10:40 UTC, where no fore-
152 shock structures are observed in the solar wind, in order to easily being able to identify
153 isolated magnetic holes. This also implies that the magnetosheath downstream of this
154 region, typically associated with the quasi-perpendicular bow shock, is in a less turbu-
155 lent state, also facilitating identification of magnetic holes there.

156   During that interval, we can identify an isolated magnetic hole in the solar wind,
157 at around 10:35 UTC, which is also observed in the downstream magnetosheath by S/C
158 3 and 4, at around 10:35:40 UTC. Below, we will take a closer look at this event, and
159 introduce several other similar observations.

3 Results

161   We will begin by presenting two detailed examples of simultaneous observations
162 of magnetic holes in the solar wind and magnetosheath. After that we will present fur-
163 ther examples in less detail, followed by some statistical results from our whole sample.

### 3.1 Example 1, 2013-01-14:10:35 UTC

165   In Figure 2 we show a more detailed view of the magnetic hole shown in Figure 1.
166 Panels (a)-(f) shows a zoomed-in interval in the same format as Figure 1, with the ad-
167 dition of the ion velocity components for S/C 4. Furthermore, the magnetic field mag-
168 nitudes have been smoothed with a 1 s running window, to remove high-frequency vari-
169 ations. Panels (g)-(j) show spacecraft positions similar to Figure 1, but for a time near
170 the centre of the zoom-in time interval. A clear, localized decrease in magnetic field strength,
171 characteristic of magnetic holes can be observed both in the solar wind by S/C 2, and
172 in the magnetosheath by S/C 3 and 4. No similar magnetic hole signature is observed
173 in S/C 1. We have calculated the relative decrease of the structures by first determin-
174 ing a background magnetic field strenght B_0 by calculating an average of the magnitude
175 of the magnetic field, with a sliding window with a width of 300 s

$$B_0(t) = \langle |\mathbf{B}(t)| \rangle_{300s}, \tag{1}$$

176   where the angular brackets stand for the averaging operation. We then calculate
177 the relative magnetic field change as

$$\frac{\Delta B}{B_0}(t) = \left\langle \frac{|\mathbf{B}(t)| - B_0}{B_0} \right\rangle_{1s}. \tag{2}$$

178   We will show time series of $\frac{\Delta B}{B_0}$ below for several events, but for the moment we
179 simply note that the minimum $\frac{\Delta B}{B_0}$ for the structures observed by S/C 2 is -0.41 and -
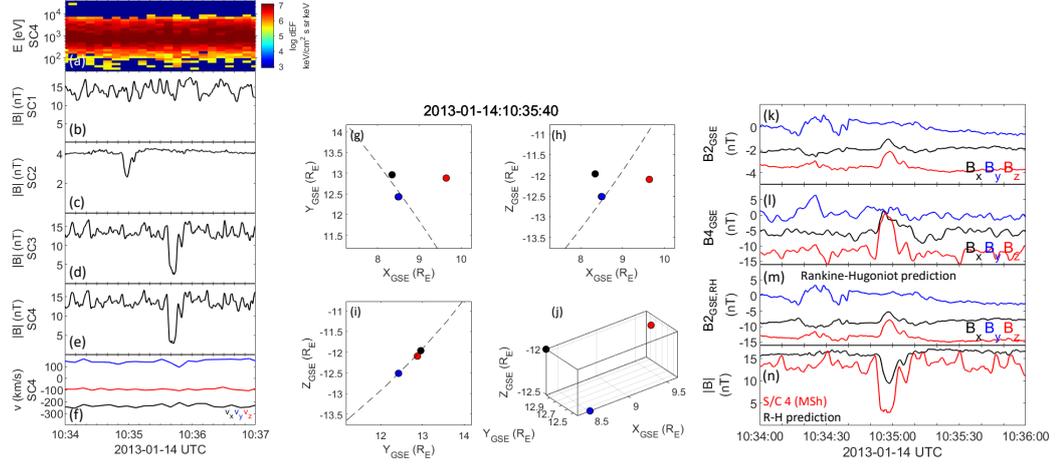

2.pdf

Figure 2. Panels (a)-(e): zoomed-in interval in the same format as Figure 1, panel (e): ion velocity components for S/C 4, panels (g)-(j): spacecraft position in the same format as Figure 1, panels (k)-(l): magnetic field components for S/C 2 and 4, in the GSE coordinate system, panel (m): RH prediction for S/C 2, panel (n): RH prediction of magnetic field strength (black), compared with magnetic field strength measured by S/C 4. The data for S/C 2 has been time shifted for easier comparison.

0.83 and -0.84 for S/C 3 and 4, respectively. We will define an event as a magnetic hole event if a localized magnetic field decrease is below -0.5 in either the solar wind or the magnetosheath region, and there is a similar structure with a decrease of at least -0.4 in the 'complementary' region (in this case the solar wind.) We therefore consider the present example to be a magnetic hole event.

The detailed morphology of magnetic holes are not known, but the fact that the magnetic hole is not observed by S/C 1 indicates that its size in the direction along the separation between S/C 2 and 3 is comparable to that separation length, i.e. around 0.5 R_E. We will make a detailed investigation of magnetic holes morphology based on Cluster multi-point measurements in a future study. We can also note that there are no large variations in the ion flow velocity associated with the magnetic hole. This is consistent with the results of Karlsson et al. (2015), who interpreted localized density increases in the magnetosheath correlated with magnetic field decreases as magnetic holes crossing the bow shock. These structures also had no associated increase in ion flow velocity, and were designated as '(slow) diamagnetic plasmoids'.

In order to study the process of the bow shock crossing in some more detail, we have also compared the downstream magnetic field signatures with the predicted signatures from applying the magnetohydrodynamic (MHD) Rankine-Hugoniot (RH) jump conditions (e.g. Priest, 2012). The RH jump conditions relate downstream and upstream values of the plasma, based on conservation laws in a fluid magnetohydrodynamic description of the plasma. Knowing the upstream conditions, it is possible to solve for the downstream fluid parameters. These solutions to the RH equations are most easily expressed in the de Hoffman-Teller (dHT) frame, which is a frame co-moving with the shock in the shock normal direction, having a velocity in the tangential direction chosen so that the upstream magnetic field is parallel to the upstream plasma flow velocity. (It is easily shown that the magnetic field and flow velocity are then parallel also downstream of the shock.) In the dHT frame, the RH jump conditions reduce to a two-dimensional problem, and

the downstream solutions can be written as (e.g. Koskinen, 2011; Oliveira, 2017; Priest, 2012)

$$\frac{\rho_d}{\rho_u} = X \tag{3}$$

$$\frac{v_{dn}}{v_{un}} = \frac{1}{X} \tag{4}$$

$$\frac{v_{dt}}{v_{ut}} = \frac{v_u^2 - v_{Au}^2}{v_u^2 - Xv_{Au}^2} \tag{5}$$

$$\frac{B_{dn}}{B_{un}} = 1 \tag{6}$$

$$\frac{B_{dt}}{B_{ut}} = \frac{X(v_u^2 - v_{Au}^2)}{v_u^2 - Xv_{Au}^2} \tag{7}$$

$$\frac{p_d}{p_u} = X + \frac{1}{2}(\gamma - 1)XM_{su}^2 v_u^2 (1 - \frac{v_d^2}{v_u^2}). \tag{8}$$

Here u and d refer to upstream and downstream values, n and t to the normal (to the bow shock) and tangential directions, ρ is the density, v is the plasma flow velocity, v_A is the Alfvén velocity, B the magnetic field strength, p the pressure, and M_s the sonic Mach number. The shock compression ratio X is often determined by solving the shock adiabatic equation (e.g. Priest, 2012). Here we will simply evaluate it from the density or velocity ratios, and use that value to solve for the downstream magnetic field. We now proceed like this:

1. We determine an lmn coordinate system by first fitting a bow shock model to the closest bow shock crossing in the data, as described above. We can then obtain the normal $\hat{\mathbf{n}}$. We let $\hat{\mathbf{l}} = \hat{\mathbf{z}}_{GSE} \times \hat{\mathbf{n}}$, and let $\hat{\mathbf{m}}$ complete the right-hand system.
2. We transform the flow velocity into the lmn coordinate system, and decompose the velocity in normal and tangential components:

$$\mathbf{v} = \mathbf{v}_n + \mathbf{v}_t = v_n\hat{\mathbf{n}} + v_t\hat{\mathbf{t}} = v_n\hat{\mathbf{n}} + v_l\hat{\mathbf{l}} + v_m\hat{\mathbf{m}}. \tag{9}$$

3. We transform into the shock frame by subtracting the shock velocity $v_{sh,n}$. This velocity can either be determined by observing the upstream and downstream velocities for the closest bow shock crossing ($v_{sh,n} = \frac{[\rho\mathbf{v}]}{[\rho]} \cdot \hat{\mathbf{n}}$), or by assuming that that velocity is zero. Thus

$$\mathbf{v}' = \mathbf{v}_n - v_{sh,n}\hat{\mathbf{n}} + \mathbf{v}_t. \tag{10}$$

4. We calculate or determine X (by using the velocities or densities).
5. We determine the deHoffman-Teller velocity for each data point $\mathbf{B}_u$. The dHT velocity is used to trasnform from the original shock frame to the dHT frame, and is given by (e.g. Kivelson et al., 1995)

$$\mathbf{v}_{HT} = \frac{\hat{\mathbf{n}} \times (\mathbf{v}_{nu} \times \mathbf{B}_u)}{\hat{\mathbf{n}} \cdot \mathbf{B}_u}. \tag{11}$$

6. We transform the velocities into the dHT frame for each data point:

$$\mathbf{v}'' = \mathbf{v}' - \mathbf{v}_{\mathbf{HT}}. \tag{12}$$

7. We calculate the downstream magnetic field.
8. We transform back into the GSE system.

The result of this procedure is shown in panels (k)-(n) in Figure 2. Here panels (k) and (l) show the magnetic field components in the GSE coordinate system, observed by

239   S/C 1 in the solar wind, and S/C 4 in the magnetosheath. The data for S/C 2 has been
240   shifted by 42 s to facilitate a comparison (also in panels (m)-(n)). Panel (m) shows the
241   solution to the RH jump conditions for the downstream values, based on the upstream
242   values observed by S/C 1, as described above. We have used the ratio of upstream and
243   downstream flow velocities observed by S/C 4 to calculate the compression ratio X. Us-
244   ing the densities instead does not change the results considerably. We have also set the
245   shock velocity to zero, since the closest shock observation is rather far removed in time.
246   Trying different shock velocities up to around 100 km/s does also not change the results
247   drastically. We can see that there is a reasonably good general agreement between the
248   downstream magnetic field predicted by the RH jump conditions and the actual down-
249   stream values observed by S/C 4. We can note that this is an example of a linear mag-
250   netic hole. We have calculated the change in magnetic field direction over the magnetic
251   hole by averaging the magnetic field components during 20 s before, and after the mag-
252   netic holes, respectively. For the solar wind measurements this gives a change of 3°, and
253   for the magnetosheath measurements 4°. Making the same calculation on the RH-predicted
254   magnetic field yields a rotation of 2°. This is expected, since if the magnetic field direc-
255   tion is similar before and after the magnetic hole observation, the relative change between
256   the normal and tangential components will be the same.

257   In panel (n) we show the magnitude of the predicted magnetic field compared to
258   the measured downstream values. The agreement is good, although the RH prediction
259   overestimates the general magnitude somewhat. The prediction also does not reproduce
260   the higher level of downstream fluctuations, which are likely to be generated locally in
261   the magnetosheath. The depth of the magnetic holes is considerably lower for the RH
262   prediction, but the minimum relative change $\frac{\Delta B}{B_0}$ is -0.42, very close to the original so-
263   lar wind value. This is again expected, since for linear magnetic holes, the direction of
264   the magnetic field vector does not seem to change much over the magnetic hole. There-
265   fore, if we are in the dHT frame, the velocity direction also does not change much, mean-
266   ing that the relative change in the normal and tangential components also remains con-
267   stant. The mismatch of $\frac{\Delta B}{B_0}$ is likely to be due to either the spacecraft crossing the mag-
268   netic hole at different distances from the minimum magnetic field strength, or changes
269   in the magnetic field configuration during the bow shock crossing not captured by the
270   RH jump conditions, which are of course based on assumptions of time stationarity and
271   a one-dimensional geometry. This will be discussed further below. However, the detailed
272   similarity between the downstream S/C 4 measurements and the RH prediction, includ-
273   ing the secondary dip at around 10:35:05 UTC, leaves little doubt that these are obser-
274   vations of the same underlying magnetic hole.

3.2 Example 2, 2015-03-03:07:01 UTC

276   Figure 3 shows a second example of a magnetic hole observed in both the solar wind
277   and the magnetosheath, in the same format as Figure 2. This time S/C 1 and 2 are sit-
278   uated in the solar wind and the magnetic hole is observed first by S/C 2 and around 15
279   s later by S/C 1 consistent with the S/C separation in the x direction. The depths $\frac{\Delta B}{B_0}$
280   of the magnetic holes are -0.89 and -0.80 for S/C 2 and 1, respectively.

281   S/C 3 and 4 are located very close to each other, both of them in the magnetosheath,
282   as determined by the wide ion distribution and the magnetic field magnitude. A mag-
283   netic hole is observed by both S/C 3 and 4, around 5 s after the observation by S/C 1.
284   This magnetic hole is of the rotational type, in contrast to the previous example, which
285   can be seen from the magnetic field components for S/C 1 and 4 shown in panels (k) and
286   (l) of Figure 3. For both spacecraft observations, the magnetic hole is located at a clear
287   magnetic field rotation/current sheet. The similarities of the magnetic holes relation to
288   the magnetic field structure between the two spacecraft is further evidence that both space-
289   craft observe the same magnetic hole. The rotation of the magnetic field over the mag-
290   netic hole is 173° for S/C 1, and 167° for S/C 4.
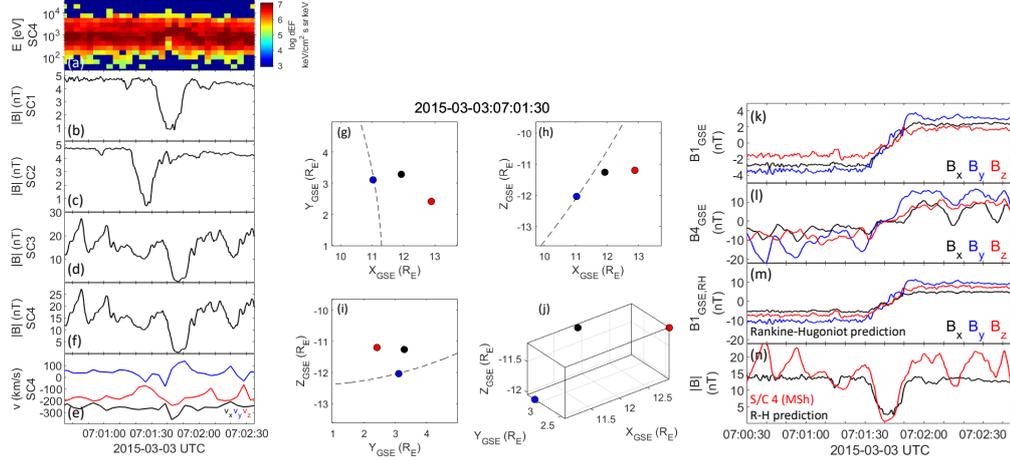

3.pdf

Figure 3. Data in same format as Figure 2, but for a rotational magnetic hole from 2015-03-03.

We have performed a similar Rankine-Hugoniot prediction of the downstream magnetic field as above, based on the S/C 1 data. The results are shown in Figure 3(m)-(n). Again the results are in good agreement with the actual magnetosheath data from S/C 4, and the rotation across the magnetic hole using the RH-predicted magnetic field is 177° verifying that the magnetic field orientation is relatively unchanged by the passage over the bow shock. The magnitude of the RH-predicted field is somewhat smaller than the S/C 4 observations, and there are large variations in the latter, which are likely due to wave activity generated locally in the magnetosheath.

3.3 Further Examples

The two examples show above are strong evidence that the same magnetic holes have been observed both in the solar wind and the magnetosheath, thus showing that magnetic holes can cross the bow shock, while keeping their basic properties relatively unchanged. In Figure 4 we show a number of further examples, in total 10 different events. For comparison, two of these examples are the events shown above. For all examples the panels show data from two S/C, one in the solar wind and one in the magnetosheath. We show both the magnitude and components of the magnetic field. In addition we show $\frac{\Delta B}{B_0}$ for the two spacecraft in question, with the data from the magnetosheath spacecraft shifted in time for easier comparison. (The time shift was determined by maximizing the cross correlation between the measurements of the magnetic field magnitude). Comparing subfigures (d) and (g) with the Rankine-Hugoniot predictions from the previous section, we can see that $\frac{\Delta B}{B_0}$ is a reasonable proxy for the RH prediction comparison between the solar wind and magnetosheath measurements. For all examples the detailed agreement between the magnetic field measurements from the solar wind and magnetosheath is strong evidence that magnetic holes cross the bow shock and enter the magnetosheath.

3.4 Statistics

We have identified in total 26 events of the type shown above. The full list of observation times are given in the auxiliary material. In Figure 5 we show the positions of the full set of magnetic holes observations. We can see that the observations cover a large part of the dayside bow shock, and show a relative good agreement with the statistical bow shock, as evidenced by panel (c).

[!h] 4.pdf
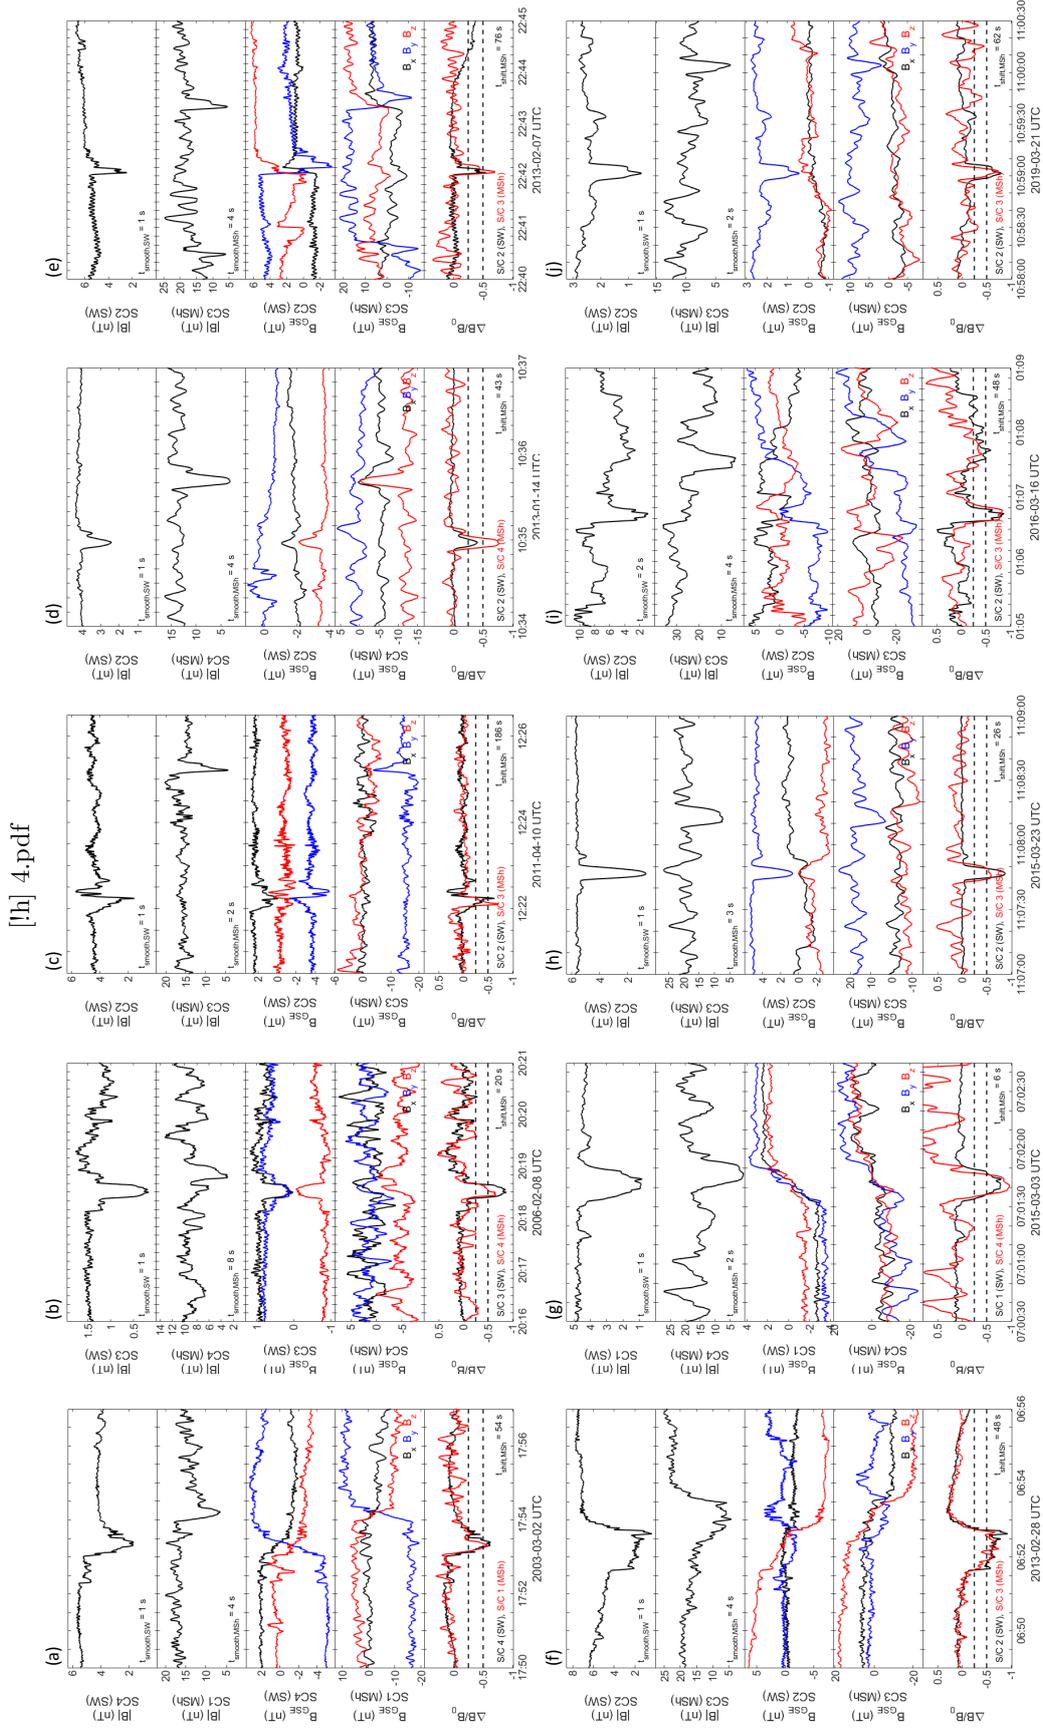

Figure 4. Ten different examples of simultaneous observation of magnetic holes in the solar wind and the magnetosheath. Each event is shown in the same format: magnetic field strength for the solar wind (SW) and magnetosheath (MSh) spacecraft, magnetic field components for the same spacecraft in GSE coordinates, and comparison of $\frac{\Delta B}{B_0}$ for the solar wind (black) and magnetosheath (red) spacecraft. The magnetosheath measurements of $\frac{\Delta B}{B_0}$ have been time shifted.
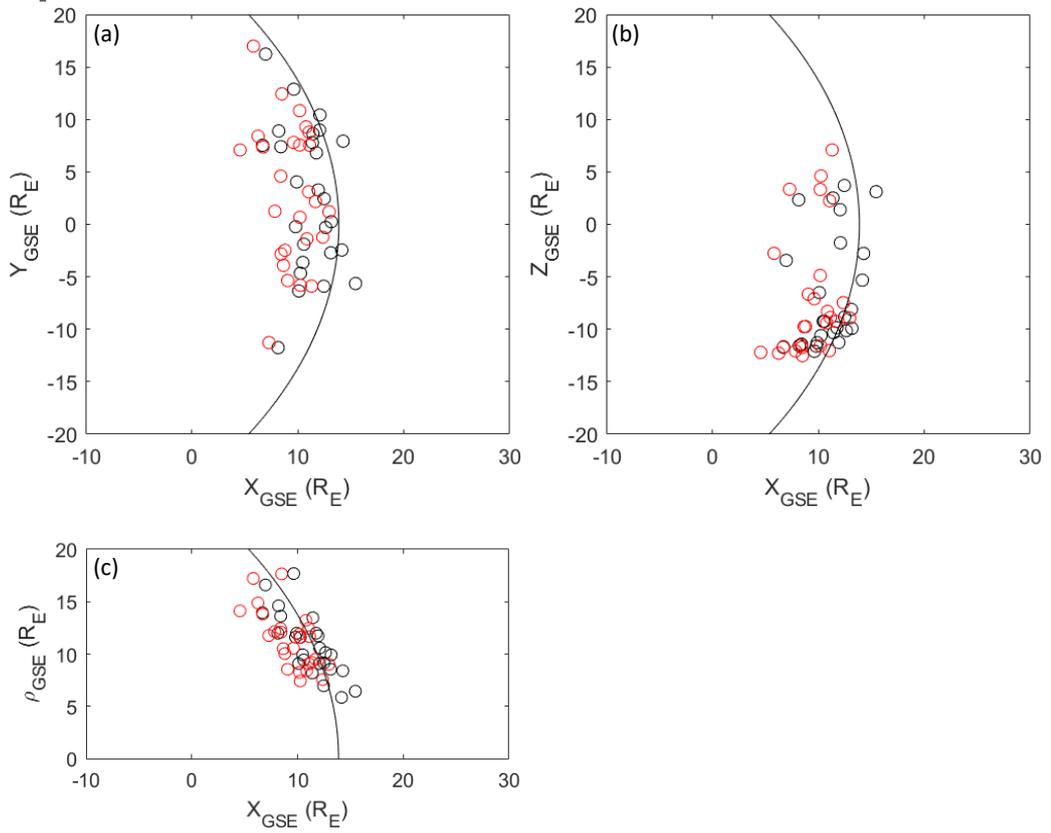

5.pdf

Figure 5. Positions of the magnetic holes in GSE x-y, x-z, and x-ρ projections ($\rho_{GSE} = \sqrt{y_{GSE}^2 + z_{GSE}^2}$). Magnetic holes encountered in the solar wind are shown in black, while magnetosheath observations are marked in red. Also shown is the bow shock position for average solar wind conditions (Kivelson et al., 1995).

In Figure 6 we show some statistical results for the full sample of 26 events. In panel (a) we show the rotation across the magnetic holes observed in the magnetosheath versus the rotation of the same magnetic hole in the solar wind. It can be seen that the sample is clearly split in two different populations, one where the solar wind magnetic holes have a rotation less than 40°, and an other where the rotation is greater than 90°. For the purposes of this paper, we will call the latter population rotational magnetic holes, and we indicate this by plotting them in red. This definition is not consistent with some earlier definitions (Karlsson et al., 2021, and references therein), but this will not be critical for our conclusions. (The triangular plots symbols will be explained below.) The other population we then call linear magnetic holes, and plot in black. We will use the same color convention in panels (b) and (c). From panel (a) it is clear that even if the correlation between the rotation of the solar wind and magnetosheath observation is not perfect, a rotational magnetic hole generally remains rotational after passing the bow shock, and the same is true for the linear magnetic holes. The only exception is the outlier with a rotation of around 150° in the solar wind, but a considerably smaller rotation in the magnetosheath. For this magnetic hole the surrounding magnetosheath was in a more turbulent state than for the other events, which resulted in a large uncertainty in the determination of the magnetic field rotation.
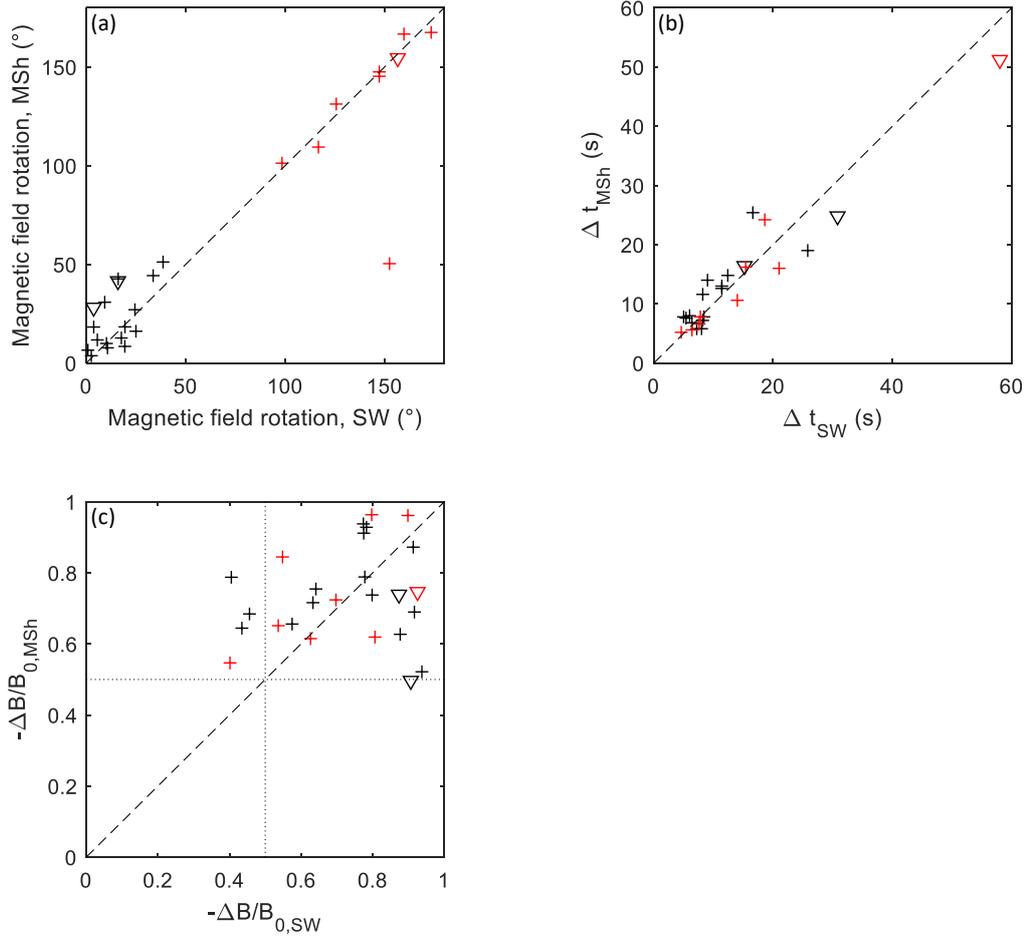

6.pdf

Figure 6. Magnetosheath values versus solar wind values for all 26 magnetic holes. Panel (a): magnetic field rotation across the magnetic hole, (b): temporal scale size, (c): magnetic field depth (with the limits of $\Delta B/B_0 = -0.5$ indicated). Black symbols represent linear magnetic holes, and red rotational holes. The triangles indicate more heavy smoothing, as described in the main text.

Figure 6(b) plots the temporal width Δt of each magnetic hole in the solar wind versus the width in the magnetosheath for the same magnetic hole. Δt is defined as the full width at the half minimum. In order to minimize effects of random fluctuations, we have smoothed the data in the solar wind using a 1 s running window, while in the magnetosheath we have used a window size of 2 s, to take into account the higher magnetic field variability. For a few magnetic holes the variability in the magnetosheath was considerably higher than for the other events, and we increased the window size to 4 or 6 s. These data points are marked with triangles. The window size for each event can be found in the table in the auxiliary material. We can see that there is a strong correlation between the temporal scale sizes in the magnetosheath and solar wind, indicating that the magnetic hole temporal scale size is approximately conserved in the crossing of the bow shock. This seems to be true for both linear and rotational magnetic holes.

351 Finally, in panel (c) we show the depth of the magnetic field, which we define as
352 the minimum of the ratio $\frac{\Delta B}{B_0}$ for each magnetic hole. Again we plot the (negative of the)
353 magnetosheath value versus the solar wind one for each magnetic hole. We have applied
354 the same smoothing as above before determining the depth. Here the spread is large, but
355 it is clear that a majority of the events fulfill the common definition of a magnetic holes
356 of $\frac{\Delta B}{B_0} < -0.5$ in both regions. Again there is no clear systematic difference between
357 linear and rotational magnetic holes.

4 Discussion

359 The Cluster multipoint measurements presented here show that both rotational and
360 linear solar wind magnetic holes can cross Earth's bow shock, while keeping their most
361 important properties relatively unchanged: their general shapes, their magnetic field ro-
362 tation, and their temporal scale size. This is consistent with the results in (Karlsson et
363 al., 2021), where it was shown that magnetic holes in the solar wind near Mercury and
364 magnetic holes in the Mercury magnetosheath had very similar distributions of magnetic
365 field rotation and temporal scale sizes. As discussed by Karlsson et al. (2021), the con-
366 servation of the temporal scale size across the bow shock is consistent with the one-dimensional
367 continuity equation.

368 In the examples shown here, including the two applications of the Rankine-Hugoniot
369 jump conditions and in the statistical results discussed above, there is no indication of
370 a more complicated interaction of the magnetic holes and the bow shock, such as the in-
371 teraction between directional discontinuities and the bow shock (e.g. Burgess & Schwartz,
372 1988; Lin, 1997). The interaction of a tangential discontinuity with the bow shock may,
373 e.g., result in Hot Flow Anomalies (HFAs), (e.g. Schwartz et al., 2000), which may have
374 quite complicated magnetosheath/downstream signatures, such as a combination of fast
375 and slow magnetosonic signatures (Eastwood et al., 2008) or magnetosheath jets (Savin
376 et al., 2012), while a rotational discontinuity may produce a downstream combination
377 of slow and intermediary shocks (Cable & Lin, 1998). For linear magnetic holes, Grib
378 and Leora (2015) modelled their interaction with the bow shock by considering the mag-
379 netic holes as bounded by two tangential discontinuities, and predicted the appearance
380 of a shock wave inside the magnetic hole.

381 There are a number of possible explanations as to why such complex interactions
382 with the bow shock are not observed here: 1. The magnetic field rotation of the rota-
383 tional magnetic holes, or the boundaries of the linear magnetic holes, are perhaps not
384 abrupt enough to be considered as discontinuities. 2. The orientation of the current sheets
385 may influence the interaction with the bow shock. It is e.g. known that HFAs are only
386 triggered by tangential discontinuities which have a normal with a large cone angle (Schwartz
387 et al., 2000). 3. HFAs are mainly triggered by tangential discontinuities, while if the ro-
388 tational magnetic holes are generated by magnetic flux annihilation by reconnection, they
389 are likely to be rotational discontinuities (if they indeed can be considered as disconti-
390 nuities). 4. There may be a confirmation bias, in that our selection criterion is that the
391 upstream and downstream signatures are similar. Perhaps there are times when rota-
392 tional solar wind magnetic holes do not penetrate the bow shock in the simple fashion
393 that our observations suggest, but have more complicated downstream/magnetosheath
394 signatures that we have discarded from our selected events. Studying the interaction of
395 both rotational and linear magnetic holes with the bow shock with MHD and hybrid sim-
396 ulations should give further insight into the magnetic hole-bow shock interaction.

397 The exception to the close upstream and downstream similarities of the magnetic
398 hole properties is the depth of the holes. While the magnetic holes have a $\frac{\Delta B}{B_0}$ of at least
399 -0.4, the correlation between the upstream and downstream values is not as strong as
400 for e.g. the temporal scale size. One explanation could be that the upstream and down-
401 stream spacecraft observe different parts of the magnetic hole, and do not probe equally

deep into the magnetic holes. This is, however, not consistent with the very good temporal scale size upstream-downstream correlation. Another possibility is that the determination of the background magnetic field, B_0, is affected by the higher magnetic field variability in the magnetosheath compared with the solar wind. Another explanation could be that there actually is some more complicated interaction between the magnetic holes and the bow shock than that implied by one-dimensional MHD (as represented by the RH jump conditions). A further possibility is discussed below.

Linear solar wind magnetic holes typically exhibit a balance between thermal and magnetic pressure, by which we understand that the total pressure is the same inside the magnetic holes as in the outside solar wind plasma (Burlaga & Lemaire, 1978; Madanian et al., 2019; Stevens & Kasper, 2007; Volwerk et al., 2021; Winterhalter et al., 1994). If the magnetic hole plasma fulfills the Rankine-Hugoniot jump conditions, this pressure balance may be disturbed by the bow shock crossing, since the tangential and normal magnetic field components are not transformed in the same way (Equations 6 and 7), and the downstream magnetic field strength therefore depends on θ_{Bn}, while the thermal pressure does not (Equation 8). Immediately after crossing the bow shock, the plasma inside a linear magnetic hole may therefore not be in pressure balance with its surroundings. This lack of pressure balance may be used as an indication that the magnetic holes are not generated locally in the magnetosheath. The effects of the lack of pressure balance will probably depend on the morphology of the magnetic hole, of which very little is known. If the magnetic holes are elongated along the background magnetic field, as results on diamagnetic plasmoids in the magnetosheath seem to indicate (Karlsson et al., 2012), the pressure dynamics may mainly take place in the magnetic field-aligned direction. Depending on the time scale of these dynamics, this could be an explanation of the difference in the magnetic hole depth between upstream and downstream observations. If the magnetic holes have similar extensions in the directions parallel and perpendicular to the background magnetic field, the pressure dynamics may also take place in the perpendicular direction. This could possibly be related to observations that have been interpreted as expansion or contraction of magnetic holes in the magnetosheath (Yao et al., 2020), although we believe that the uncertainties of these observations are large. We plan to further study the pressure balance of magnetic holes in the magnetosheath, using MMS burst data (Baker et al., 2016), in the near future.

Assuming that the magnetic holes are frozen in to the plasma flow in the solar wind, the fact that the temporal scale sizes are the same in the magnetosheath indicates that the magnetic holes are then also frozen in to the magnetosheath plasma. Some magnetosheath magnetic holes may therefore encounter the magnetopause, and interact with it. If the magnetic holes are associated with a density increase (as for the diamagnetic plasmoids), they will also have a larger dynamic pressure than the surrounding magnetosheath plasma. It can be expected that the magnetic hole–magnetopause interaction can result in similar phenomena as those created by magnetosheath jets, for example triggered localized reconnection, magnetopause surface and compressional waves, impulsive penetration, modified ionspheric flows and even aurora (Plaschke, Hietala, et al., 2018). This will be the subject of further studies.

5 Summary and Conclusions

We have used Cluster multipoint measurements to show that both linear and rotational magnetic holes can cross the bow shock and enter the magnetosheath. For the 26 events we have identified, their properties (general shape, temporal scale size, and magnetic field rotation across the hole) are quite unchanged by the passage of the bow shock. The exception is the magnetic field depth, which can vary considerably between the upstream and downstream observations. This may possibly be related to the change in relation between the thermal and magnetic pressures, expected from the MHD Rankine-Hugoniot jump conditions. In general, the magnetic holes studied here show no signs of

a more complicated interaction with the bow shock than expected by the jump conditions. The results here support the interpretation that magnetic holes found in the magnetosheaths of Earth and Mercury are of solar wind origin, and are not generated locally in the magnetosheath (Karlsson et al., 2012; Karlsson et al., 2015, 2016; Karlsson et al., 2021). The increased dynamic pressure associated with magnetosheath magnetic holes may interact with the magnetopause in similar ways to magnetosheath jets, which represents a new type of solar wind - magnetosphere interactions that needs to be further studied.
