20   **Abstract**

21   The Himalayan orogen exposes a range of metamorphosed assemblages, from low-grade Indian
22   shelf sediments of the Tethyan Formation to eclogite and ultra-high pressure rocks documented
23   near the suture zone between the Indian craton and Asian subcontinent. Barrovian-grade pelites
24   and mafic protoliths are exposed in the Himalayan core and include the Greater Himalayan
25   Crystallines and Lesser Himalayan Formations. These units are separated by the Main Central
26   Thrust (MCT). This fault system accommodated a significant amount of India-Asia convergence
27   and is the focus of several models that explore ideas about the development of the range and
28   collisional belts in general. These units provide critical information regarding the mechanisms of
29   heat transfer within collisional belts. Garnets collected across the MCT record their growth
30   history through changes in chemistry. These chemical changes can be extracted and modeled
31   using a variety of thermodynamic approaches. This paper reviews the geological framework of
32   the Himalayas with a focus on the protolith of its metamorphosed assemblages. It describes and
33   applies particular thermobarometric techniques to decipher the metamorphic history of several
34   garnet-bearing rocks collected across the MCT in central Nepal. Comparisons are made between
35   the results of previously-reported conventional rim P-T conditions and P-T paths extracted using
36   the Gibb's method to isopleth thermobarometry and high-resolution P-T path modeling using the
37   same data and assemblages. Predictions of the paths on garnet zoning are also presented for the
38   high-resolution P-T path modeling and Gibb's method using the program TheriaG. Although the
39   approaches yield different absolute conditions and P-T path shapes, all are consistent with the

40   development of the MCT shear zone due to imbrication of distinct rock packages. Greater
41   Himalayan Crystalline garnets experienced higher-grade conditions that make extracting its P-T
42   conditions and paths a challenge. Lesser Himalayan garnets appear to behave as closed systems
43   and are ideally suited for thermodynamic approaches.

1   Introduction

45   Nineteenth-century geologists studying the Himalayas perceived an anomalous geologic
46   relationship that appeared to contradict two commonly accepted principles: the oldest rocks in a
47   sedimentary succession are found at the base of the pile, and metamorphosed strata are older than
48   unmetamorphosed. The Main Central Thrust (MCT), located at the base of the Himalayan break
49   in slope, places lower-grade Lesser Himalayan Formation (LHF) metasediments beneath high-
50   grade gneisses of the Greater Himalayan Crystallines (GHC) (Figure 1 and Figure 2).
51   Exploration of the Himal Pradesh region in northern India surprised the pioneering geologists
52   (Medicott, 1864; Oldham, 1883; Middlemiss, 1887) who saw the highest-grade, and thus
53   supposedly oldest rocks, form the tallest peaks:

54   "Now the belief which is at present so rapidly gaining ground that metamorphic strata are
55   presumably older than unmetamorphosed strata makes one at first glance assume the strong
56   probability in favor of the inner schistose series [Greater Himalayan Crystallines] being of
57   much greater age than the outer zone of formations [Lesser Himalaya]. But no sooner has this
58   a priori probability obtained a firm hold of the mind than a rude shock is given to it by the
59   discovery that at every point round the schistose area the Outer formations appear to dip
60   towards and under the schistose series at steep angles (50°-60°), whilst the schistose series
61   itself is disposed apparently…upon the top of the Outer Formations, and culminating in a
62   capping of gneissose rock on the summit of Kalogarhi mountain, the highest point in the
63   neighborhood (Middlemiss, 1887)."

64   The recognition of widespread thrusting within the Himalaya was largely based on the
65   observations (von Loczy, 1907; Pilgrim & West, 1928; Auden, 1937; Heim and Gansser, 1939)
66   and the orogen's "inverted metamorphism," an increase in metamorphic intensity towards higher
67   structural levels, appeared resolved by invoking compressional/contractional tectonics and the
68   thrusting of the GHC unit on top of the LHF. However, future studies indicated that the kyanite
69   isograd remained unbroken across the MCT, and its footwall is characterized by an inverted
70   geotherm (Figure 3) (Ray, 1947; Gansser, 1964; LeFort, 1975; Pêcher, 1989; England et al.,
71   1992). The idea of Himalayan inverted metamorphism reemerged but was relocated to the MCT
72   footwall.

73   Inverted metamorphic gradients suggest the presence of wholly overturned strata or heat
74   sources that counteract the influence of the asthenosphere (e.g., England & Molnar, 1993;
75   Jamieson et al., 1996; Grasemann & Vannay, 1999; Kidder et al., 2013). The cause of the
76   phenomenon has implications for establishing mechanisms of heat transfer within collisional
77   belts and the role of heat sources, such as shear heating in fault zones, heat advection by
78   magmas, radiogenic heating, and asthenospheric input. Inverted metamorphism has long been
79   associated with areas of extensive thrust faulting, where heat is thought to flow from a hot upper
80   plate to a colder lower plate (Ernst, 1973; Graham & England, 1976; Spear et al., 1995). Some
81   models of Himalayan orogenesis link the apparently anomalous geothermal gradient spatially
82   and temporally with motion along the MCT, whereas others suggest a juxtaposition of previously

83 metamorphosed sequences (Searle & Rex, 1989; Harrison et al., 1999; Hodges, 2000; Dasgupta
84 et al., 2004; Larson et al., 2015).

85   The MCT has accommodated a significant amount of Indo-Asian convergence (e.g.,
86 Schelling & Arita, 1991; Yin & Harrison, 2000; Yin, 2006; Tobgay et al., 2012; Roberts et al.,
87 2020), but other large-scale structures, including crustal-scale strike-slip faults to the north,
88 active thrusts to the south, and the Main Himalayan Thrust (MHT) decollement compete for
89 strain accommodation (Figure 2). The MCT has long been thought to be presently quiescent (Ye
90 et al., 1981; Ni & Barazangi, 1984; Schelling & Arita, 1991; England et al., 1992). However,
91 some earthquakes, like the 2015 Nepal (Gorkha) and 1991 Uttarkashi (Garhwal) events,
92 challenge the notion, as their epicenters and epicenters of their aftershocks are modeled to zones
93 within the LHF (Thakur & Kumar, 1994; Jain & Chander, 1995; Kayal, 1996; Gupta et al., 2015;
94 Bai et al., 2016; Catlos et al., 2020). The MCT has also been linked to the generation of
95 numerous geologic elements that characterize the Himalayan range, including hanging wall
96 anatectic granitoids and crustal-scale extension found in association with the GHC (e.g., Burg et
97 al., 1984; Valdiya, 1988; Burchfiel et al., 1992; Harrison et al., 1997; Kawakami et al., 2019).

98   Studies of the MCT hanging wall indicate the unit has discontinuities possibly related to
99 internal structures (e.g., western Nepal, Carosi et al., 2010; Montomoli et al., 2013; Braden et al.,
100 2017; central Nepal, Cottle et al., 2015; Wang et al., 2013; 2016; Rapa et al., 2018; Larson et al.,
101 2015; Sikkim, Chakraborty et al., 2019; NW India, Iaccarino et al., 2020; Benetti et al., 2021; see
102 discussions in Mukherjee et al., 2012; Larson et al., 2013; Montomoli et al., 2015). The nature of
103 these cryptic discontinuities is unclear and could be due to unmapped faults or shear zones or
104 inheritance of pre-existing basement structures (e.g., Cottle et al., 2015). Their presence
105 enhances the complexity of the Himalayan orogenic system as their activity could have
106 significantly disrupted geotherms within the GHC core during its exhumation. This is a scenario
107 that is not accounted for in the channel flow model for the extrusion of the Himalayan core (e.g.,
108 Benetti et al., 2021; Maiti & Mandal, 2021). Understanding when Himalayan fault systems were
109 active is critical for deciphering the processes involved during convergence.

110   The metamorphic history of the Himalayas has been the focus of sustained attention for
111 almost seventy-five years (e.g., Ray, 1947). Garnet-bearing assemblages have long been using to
112 test hypotheses proposed for the origin of MCT inverted metamorphism, understand the slip
113 history of the MCT and the dynamics of Himalayan convergence. The focus includes generating
114 the peak pressure-temperature (P-T) conditions and paths that rocks followed as they were
115 metamorphosed during Indo-Asia collision (e.g., Brunel and Kienast, 1986; Hodges et al., 1988;
116 Hodges and Silverberg, 1988; Hubbard, 1989; Inger and Harris, 1992; Hodges et al., 1993;
117 Metcalfe, 1993; Pognante and Benna, 1993; Kaneko, 1995; Macfarlane, 1995; Coleman, 1996;
118 Vannay and Hodges, 1996; Vannay and Grasemann, 1998; Manickavasagam et al., 1999; Catlos
119 et al., 2001; Kohn et al., 2001; Kohn, 2008; Phukon et al., 2019; Waters, 2019; Iaccarino et al.,
120 2020; Catlos et al., 2018; 2020).

121   As a universal outcome, models for the development of the Himalayas predict the P-T
122 paths that rocks follow as they track the conditions they experienced during displacement.
123 Common approaches to generate Himalayan P-T paths have included connecting peak
124 metamorphic conditions of individual rocks, inferring from mineral assemblages,
125 pseudosections, or Gibbs method thermodynamic modeling. Some rocks yield problematic P-T
126 estimates based on (1) a lack of evidence of phases in equilibrium among phases, (2) the
127 application of barometers to inappropriate (uncalibrated) mineral compositions, and (3)

128 calculated conditions that appear at odds to observed mineral assemblages and structural data
129 (e.g., Kohn & Spear, 2000; Kohn, 2008). P-T paths and absolute peak P-T conditions may not be
130 diagnostic of tectonic processes involved (e.g., Gervais & Brown, 2011). Low-resolution P-T
131 paths can be limited in their ability to test ideas regarding lithospheric response to perturbations,
132 including motion within fault zones. However, this type of information can be used to
133 supplement other data, such as the timing of deformation or strain recorded in microstructures
134 (see Kohn, 2016; Rolfo et al., 2014).

135   This paper has two goals. The first is to review the geological framework of the
136 Himalayas with a focus on the protolith of its metamorphosed assemblages. The second is to
137 describe and apply particular thermobarometric approaches to decipher the metamorphic history
138 of garnet-bearing rocks collected from the central portion of the range across the MCT using data
139 published in the literature (Darondi Khola, Figure 3, Figure 4, Figure 5) (Kohn et al., 2001). A
140 range of approaches are available to obtain P-T and time garnet growth (P-T-t data) (see review
141 by Waters, 2019). The Darondi Khola case study compares conventional and isopleth
142 thermobarometry in terms of their outcomes and insights and presents new P-T paths from
143 metamorphosed garnet-bearing rocks using previously collected data. Garnet-bearing pelitic
144 assemblages exposed in units across the Himalayas contain information regarding their history
145 that can be extracted and applied to test models developed to decipher the crustal response
146 during orogeny.

2   Geological Background

148   The Himalayan arc extends ~2400 km from Nanga Parbat (8138 m) in the west to
149 Namche Barwa (7756 m) in the east (e.g., Le Fort, 1996) (Figure 1 and Figure 2). This region
150 includes the independent kingdoms of Nepal and Bhutan and parts of Pakistan, India, and China.
151 The orogen forms a sharp transition between the average ~5 km-high, arid Tibetan plateau and
152 the warmer, wetter Indian lowlands and is comprised of roughly parallel, crustal-scale fault
153 systems that bound distinctive lithologic units along strike (DiPietro & Pogue, 2004; Yin, 2006).
154 These units have Indian affinity and experienced variable degrees of metamorphism before their
155 assembly with Asia.

2.1 Geological framework before collision

157   The Indian subcontinent initiates rifting from other continents and fragments associated
158 with Gondwana during the Early Cretaceous (140-130 Ma, e.g., Scotese et al., 1988; Jadoul et
159 al., 1998; Hu et al., 2010). Evidence for Early Cretaceous rift- and plume-related alkaline and
160 basaltic volcanism exists within the LHF, which extends the entire length of the Himalayas, and
161 is the oldest stratigraphically lowest unit (e.g., Sakai et al., 2013; Bhandari et al., 2019). The
162 LHF is considered the MCT footwall and Main Boundary Thrust (MBT) sheet (Figure 1 and
163 Figure 2) (Dey et al., 2020). It is mainly comprised of Paleoproterozoic Gondwana-associated
164 sediments that experienced deposition and granite intrusion centered around 1800 Ma (e.g.,
165 Trivedi et al., 1984; Tripathi & Singh, 1987; Parrish & Hodges, 1996; Miller et al., 2000;
166 DeCelles et al., 2004; Kohn et al., 2010; Martin et al., 2011; McKenzie et al., 2011; Long et al.,
167 2011; Sakai et al., 2013; Khanal et al., 2014; Mandal et al., 2016). The depositional environment
168 is a passive-margin, shallow-water coastal, fluvial, volcanoclastic (e.g., Parrish & Hodges, 1996;
169 Ahmad et al., 1999; Martin et al., 2011; Sakai et al., 2013; Bhandari et al., 2019). However, the
170 lower section of the LHF may have formed in a continental arc on the northern margin of the
171 Indian plate (Kohn et al., 2010; Mandal et al., 2016). In some locations, rift-related alkaline

172   trachytic lava and pillow-bearing volcanic rocks are interbedded with pebble conglomerates and
173   black shales, and signatures of significant asthenosphere upwelling are evident using
174   geochemical proxies (e.g., Ahmad et al., 1999; Larson et al., 2019; Bhandari et al., 2019).

175   The stratigraphic classification of the Proterozoic succession of Lesser Himalaya is yet to
176   be defined following the Code of Stratigraphic Nomenclature, and orogen-scale correlations
177   along strike are hindered by uncertainties (Myrow et al., 2006; Long et al., 2011; Mandal et al.,
178   2016; Dey et al., 2020). Sedimentation was long-lasting, but a lack of fossiliferous assemblages
179   makes correlating specific units problematic (Upreti, 1999; Martin et al., 2011; Long et al.,
180   2011). Detrital zircon geochronology and stable isotopic analysis of suitable assemblages assist
181   in this regard (e.g., Long et al., 2011; Martin et al., 2011; Sakai et al., 2013). A series of augen
182   gneisses (the Melung Salleri or Phaplu Augen Gneiss of eastern Nepal and NW India, the Ulleri
183   of central Nepal, or Chainpurplay in western Nepal) distinguish different levels of the MCT
184   shear zone and LHF stratigraphy (Figure 3, Figure 4, Figure 5) (Kohn et al., 2010; Dyck et al.,
185   2019; Jharendra & Paudyal, 2019). These gneisses have ages from 2.2 Ga to 900 Ma (e.g., Le
186   Fort & Rai, 1999; DeCelles et al., 2000; Catlos et al., 2002; Kohn et al., 2010) and define the
187   base of the MCT shear zone in some interpretations. A Permian-Cambrian unconformity is
188   recognized in NW India, Nepal, and Bhutan (e.g., Bhargava et al., 2011; Martin et al., 2011;
189   Long et al., 2011). Some have related its presence and Cambro-Ordovician granites found in
190   GHC and LHF units to a pre-Tertiary orogeny (Gehrels et al., 2003; 2006; Cawood et al., 2007;
191   Bhargava et al., 2011).

192   The GHC protolith is a clastic sedimentary sequence intruded by Cambro-Ordovician
193   granitoids (e.g., Trivedi et al., 1984; Bhargava & Bassi, 1994; Parrish & Hodges, 1996; Upreti &
194   Le Fort, 1999; DeCelles et al., 2004; Dyck et al., 2019). The depositional age is bracketed
195   between the age of the youngest detrital zircons (~800-600 Ma) and granite intrusions (~500-460
196   Ma) (Ahmad et al., 2000; DeCelles et al., 2000; DeCelles et al., 2004; Martin et al., 2005; Dyck
197   et al., 2019). Whole-rock Nd isotopes distinguish GHC [εNd(0) -19 to -12, average -16] from
198   LHF affinities [εNd(0) -20 to -26, average -21.5] (Robinson et al., 2001; Martin et al., 2005). The
199   GHC detrital zircons may have originated from the East African portion of the Pan-African
200   orogeny (Arabian-Nubian Shield), uplifted during the Neoproterozoic (DeCelles et al., 2000;
201   2004), or from the late Mesoproterozoic terranes of Western Australia and East Antarctica
202   (Circum-East Antarctic Orogen, Upreti & Yoshida, 2005; Yoshida & Upreti, 2006). The GHC
203   has been modeled as unconformably deposited on the LHF (Parrish & Hodges, 1996) or
204   tectonically juxtaposed (Upreti & Le Fort, 1999; DeCelles et al., 2000). The similarity in
205   Cambrian ages between the LHF and GHC suggest they may be part of a shared depositional
206   environment, with the LHF as proximal and the GHC as distal (Brookfield, 1993; Parish &
207   Hodges, 1996; Corfield & Searle, 2000; Myrow et al., 2003; Myrow et al., 2006; Long et al.,
208   2011). Alternatively, the GHC may have been a distinct basement unit separating the LHF from
209   the Tethyan metasediments (Saxena, 1971; Aharon et al., 1987) or an exotic terrane involved in a
210   pre-Himalayan collision (DeCelles et al., 2000; Gehrels et al., 2003).

211   Tethyan sedimentary and metasedimentary rocks are bounded to the north by the Indus
212   Yarlung-Tsangpo suture zone (also Yarlung Zangbo Ophiolite Zone, Liu et al. 2010) (Gansser,
213   1964; Dewey & Bird, 1970; Burg et al., 1984; Yin et al., 1994; Quidelleur et al., 1997; Zhang et
214   al., 2004; Yin, 2006; Zyabrev et al., 2008), and to the south by the GHC or South Tibetan
215   Detachment System (STDS) (Figure 1 and Figure 2) (e.g., Makovsky & Klemperer, 1996; Wu et
216   al., 1998; Searle, 2010; Long et al., 2017; Montomoli et al., 2017; Hughes et al., 2018; Kellett et

217 al., 2018; Long et al., 2019). The Great Counter Thrust (or the Renbu-Zedong Thrust or
218 Himalayan Backthrust) is mapped south of the zone also works to accommodate crustal
219 shortening (Yin et al., 1999; Yin, 2006; Aikman et al., 2008). The Tethyan unit has long been
220 considered as a contiguous stratigraphic cover of the GHC (Bodenhausen et al., 1964; Bordet et
221 al., 1971; Stöcklin, 1980; Garzanti & Pagni Frette, 1991; Brookfield, 1993; Liu & Einsele, 1994;
222 Fuchs & Linner, 1995; Vannay & Steck, 1995; Garzanti, 1999; Dyck et al., 2019), and the suture
223 zone marks the geological boundary separating rocks of Indian and Asian affinity (e.g., Gansser,
224 1981; Yin & Harrison, 2000). In NW India, the Tethyan Formation may be in thrust contact with
225 the LHF (Webb et al., 2007). The Tethyan Formation consists of Paleoproterozoic to Eocene
226 Indian shelf sediments (marine, fossiliferous strata) interbedded with Paleozoic and Mesozoic
227 volcanic assemblages (Bassoullet et al., 1980; Brookfield, 1993; Yin, 2006; Bhargava & Singh,
228 2020). The unit has been divided into four sequences: a Proterozoic to Devonian pre-rift, a
229 Carboniferous–Lower Jurassic rift and post-rift, Jurassic–Cretaceous passive continental margin
230 sequence, and an uppermost Cretaceous–Eocene syn-collision sequence (Liu & Einsele, 1994;
231 Garzanti, 1999; Yin, 2006). Tethyan Formation lithostratigraphy changes both along and
232 perpendicular to the Himalayan orogeny (Brookfield, 1993; Yin, 2006). In some locations, the
233 unit has undergone pre-Himalaya low-grade to greenschist facies metamorphism (e.g., Crouzet et
234 al., 2007; Dunkl et al., 2011; Montomoli et al., 2017) and the latest Cretaceous to Paleocene
235 sequence of the formation records the obduction of ophiolitic material (Allègre et al., 1984; Burg
236 et al., 1987; Willems et al., 1996; Gnos et al., 1997; Makovsky et al., 1999; Aitchison et al.,
237 2000; Ding et al., 2005).

2.2 Timing of major metamorphic events and fault systems

2.2.1 Collision and metamorphism in the Tethyan Formation

240   The Indian subcontinent moves over 60° latitude north towards Asia during the mid-
241 Mesozoic to Eocene, closing the ancient Neo-Tethyan Ocean (e.g., Burg, 2011). The Early
242 Cretaceous (140-130 Ma) is often cited as the time when the Indian subcontinent initiates rifting
243 from other continents and fragments associated with Gondwana (e.g., Scotese et al., 1988; Jadoul
244 et al., 1998; Hu et al., 2010). Remnants of Neo-Tethyan ophiolites are present across the
245 Himalayas and provide information regarding the timing and processes involved during Indo-
246 Asia collision and the nature of Neo-Tethyan ocean crust and upper mantle (e.g., Hébert et al.,
247 2012; Hu et al., 2016; Catlos et al., 2019). Based on data from these ophiolites, a Late
248 Cretaceous intra-oceanic arc has been suggested to be present within the Neo-Tethyan Ocean
249 near the paleo-equator (e.g., Reuber, 1986; Abrajevitch et al., 2005; Metcalfe, 2009; Dai et al.,
250 2011; Siddiqui et al., 2012; Siddiqui et al., 2017) or ~30°N (Zhu et al., 2013). The arc is recorded
251 by the Samail (Oman), Zagros (Iran), Chagai–Raskoh (western Pakistan, southern Iran, eastern
252 Afghanistan), Kandahar and Kohistan–Ladakh, Dazhuqu, and Zhongba arcs (Brookfield and
253 Reynolds, 1981; Bhutani et al., 2004; Abrajevitch et al., 2005; Dai et al., 2011; Siddiqui et al.,
254 2012; Baxter et al., 2016). Paleogeographic reconstructions of Lawver et al. (2018) restrict the
255 location of the intra-oceanic arc to the south of the Lhasa Terrane, although others suggest the
256 Lhasa Terrane had already accreted onto other Tibetan-related continental fragments by the Late
257 Jurassic-Early Cretaceous (Rolland, 2002; Kapp et al., 2003, 2007; Guynn et al., 2006; Zhu et
258 al., 2013). Alternatively, the Lhasa Terrane accreted just before the final collisional event in the
259 Paleocene (54.9±2.3 Ma and 40.0±3.3 Ma; Yang et al., 2015; 61 Ma and ~53-48 Ma; Yuan et al.,
260 2020). Multiple arcs, besides the Lhasa Terrane, may also have been present (e.g., Zyabrev et al.,
261 2008). The oldest portion of the Neo-Tethyan domain is Late Triassic to Late Cretaceous (Sinha-

262 Roy, 1982; Şengör and Atayman, 2009; Cao et al., 2018) and is sometimes termed the Ceno-
263 Tethyan Ocean (Metcalfe, 1999; Matsuoka et al., 2002; Wakita and Metcalfe, 2005). The
264 Yarlung-Tsangpo suture zone itself is mapped as the zone of the closure of the Ceno-Tethyan
265 Ocean (e.g., Metcalfe, 1999; 2009; 2013).

266 The timing of initial collision varies along strike of the range but is often cited as during
267 the Paleocene (Patriat & Achache, 1984; Klootwijk et al., 1992; Rowley, 1996; Yin & Harrison,
268 2000; Najman et al., 2001, 2002, 2003; Zhu et al., 2005; Ding et al., 2005; Yang et al., 2015; Hu
269 et al., 2016). Much younger constraints are also suggested (e.g., Eocene/Oligocene boundary,
270 Aitchison et al., 2007) and a division between a soft (Paleocene) and hard collision (25-20 Ma,
271 van Hinsbergen et al. 2012; see review in Parsons et al., 2020). In the hard scenario of Indo-Asia
272 collision, the Tethyan unit represents the northern extension of the Indian subcontinent
273 (Brookfield, 1993; Yin & Harrison, 2000; Myrow et al., 2003, Hughes et al., 2005; Myrow et al.,
274 2009; Myrow et al., 2015; Hughes, 2016). Others suggest the Tethyan formation may have been
275 an independent terrane in the Mesozoic (DeCelles et al., 2000; see review in Yuan et al., 2020).
276 Parsons et al. (2020) note that little progress has been made to resolve the differences between
277 models of Indo-Asia collision. Gehrels et al. (2003) indicates that ascertaining the relative
278 contributions of early Paleozoic versus Tertiary tectonism poses a significant challenge in
279 understanding the Himalayan orogen. To understand which model is relevant requires
280 understanding the metamorphic and timing history of fault systems that were active during
281 collision. The Great Counter Thrust, which bounds the upper portion of the Tethyan Formation
282 along much of its strike (Figure 1), is significantly younger than the Paleocene ages of Indo-Asia
283 collision. This structure shows activity primarily during the Miocene (20-13 Ma) across the
284 western and central Himalayas (see review in Yin, 2006).

285 Compilations regarding the Tethyan Formation's metamorphic history collected along
286 strike suggest the Tethyan sequences have experienced multiple (4-5) deformation events,
287 although the timing of these episodes is poorly constrained (Aikman et al., 2008; Dunkl et al.,
288 2011). Studies focusing on the low-grade history reveal Early Cretaceous pre-collisional
289 metamorphism (e.g., Crouzet et al., 2007; Dunkl et al., 2011). Eocene greenschist to amphibolite
290 facies metamorphism is recorded in portions of the unit and record conditions likely related to
291 the onset of collision (580-600°C, 5-8 kbar) (Dunkl et al., 2011; Catlos et al., 2020). Paleocene
292 radiometric ages related to collision are found in the Spongtang ophiolite (Figure 1) (64.3±0.8
293 Ma and 42.4±0.5 Ma, zircon U-Pb ages, Catlos et al., 2019) and in a Tethyan Formation garnet
294 (50.3±0.6 Ma; Catlos et al., 2020). The collisional event is also recorded by eclogite, high-
295 pressure (HP) and ultra-high pressure (UHP) rocks documented within the Tethyan Formation
296 near the suture zone (e.g., Guillot et al., 2008; Laskowski et al., 2016). In some locations, HP
297 assemblages record multiple metamorphic stages (e.g., Chen et al., 2021). Oligo-Miocene anchi-
298 to epizonal metamorphism and alteration are related to crustal shortening during this time,
299 whereas rocks at the base of the unit record Miocene STDS motion and gneiss dome exhumation
300 (e.g., Dunkl et al., 2011). Oligocene- to Miocene-age contact metamorphism marks the onset of
301 the intrusion of some North Himalayan granitic bodies and gneiss domes (e.g., Guillot et al.,
302 1995, 1999; Liu et al., 2016; Gao et al., 2016; Lihter et al., 2020). The onset of the north-dipping
303 STDS and its associated imbrications (Figure 1) is often constrained to the Miocene (Carosi et
304 al., 1998, 1999a, 1999b; Searle, 1999; Sachan et al., 2010; Iaccarino et al., 2017; Long et al.,
305 2017; Montomoli et al., 2017; Kellett et al., 2018; Iaccarino et al., 2020). However, at some
306 locations, the GHC shows a transitional relationship with limestone of the Tethys sediments and
307 metamorphic grade remains unchanged across the STDS with stratigraphy and lithology

308 excluding a distinct fault boundary (e.g., Bordet et al., 1975; Stöcklin, 1980; Fuchs et al., 1988;
309 Schneider & Masch, 1993; Vannay & Steck, 1995; Cooper et al., 2012; Long et al., 2017). Long
310 et al. (2019) suggest that extensional motion associated with the STDS in Bhutan occurs both
311 within the GHC and Tethyan units.

2.2.2 The GHC Eohimalayan and Neohimalayan events

313 The GHC is mainly comprised kyanite- to sillimanite- grade gneisses intruded by High
314 Himalayan leucogranites in structurally higher levels (e.g., Upreti, 1999; Searle et al., 2006;
315 Sachan et al., 2010; Wu et al., 2020). The GHC is generally divided into different units, although
316 the assemblages that comprise its sections differ along strike (Le Fort, 1975; Myrow et al., 2003;
317 Yin, 2006). In central Nepal (Guillot, 1999), the upper Formation III consists of augen
318 orthogneisses, whereas the middle Formation II are calc-silicate gneisses and marbles, and the
319 basal Formation I are kyanite- and sillimanite-bearing metapelites, gneisses, and
320 metagreywackes with abundant quartzite. The division of the package into three units mirrors the
321 nomenclature ~250 km east (Lombardo et al., 1993; Pognante & Benna, 1993; Carosi et al.,
322 1999a), although the assemblages differ from that of central Nepal. In eastern Nepal, the upper
323 Black Gneiss is comprised of biotite-sillimanite paragneisses with metaconglomerates and
324 quartzite layers. The middle Namche Migmatite Orthogneiss contains granite-granodiorite
325 sillimanite-bearing orthogneisses. The Barun Gneiss at the base is a migmatized paragneiss with
326 minor metabasites, calc-silicate rocks, and marbles. In the Garhwal Himalaya, the Vaikrita
327 Group is the analog to the GHC (e.g., Ahmad et al., 2000). Early observations, the unit's
328 complex metamorphic history, and possibility of out-of-sequence thrusting at higher levels led
329 Stöcklin (1980) to doubt the assumption of a three-tiered, laterally-continuous,
330 tectonostratigraphic framework. More recent thermobarometric data and P-T-t paths from garnet-
331 bearing assemblages from the GHC unit indicate the unit itself has discontinuities related to
332 internal structures that overlap in age with MCT motion (Carosi et al., 2010; Montomoli et al.,
333 2013; Wang et al., 2013; Larson et al., 2015; Montomoli et al., 2015; Carosi et al., 2016; Wang
334 et al., 2016; Braden et al., 2017; Rapa et al., 2018; Chakraborty et al., 2019; Benetti et al., 2021).

335 A Tertiary history involving two metamorphic episodes has been proposed for the GHC
336 (see Pêcher & Le Fort, 1986; Metcalfe, 1993; Pognante & Benna, 1993; Wiesmayr &
337 Grasemann, 2002; Carosi et al., 1999b; Lombardo & Rolfo, 2000; Hodges, 2000; Wiesmayr &
338 Grasemann, 2002; Cottle et al., 2009; Kohn, 2014; Robyr & Lanari, 2020). The first stage
339 (Eocene-Oligocene) of Barrovian-type metamorphism, termed the Eohimalayan event,
340 corresponds to the nappe's burial beneath Asia and is best preserved near the base of the unit
341 (e.g., Pêcher, 1989; Hodges et al., 1994; Wiesmayr & Grasemann, 2002). During this stage, the
342 base of the unit reached garnet-grade conditions (550-750□C and at least 8-10 kbar, e.g.,
343 Pognante & Benna, 1993; Hodges et al., 1994). Thrusting may have been accommodated by a
344 fault system considered a proto-STDS that reactivated as a normal fault during the second stage
345 in the Miocene (e.g., Vannay & Hodges, 1996; Wiesmayr & Grasemann, 2002; DiPietro &
346 Pogue, 2004). The locations where this scenario has been proposed show mylonitic contractional
347 fabrics overprinted by extensional structures and include the Himachal Pradesh, NW India
348 (Vannay & Grasemann, 1998), Zanskar, NW India (Patel et al., 1993), and the Kali Gandaki,
349 central Nepal (Vannay & Hodges, 1996). Note that even earlier events may have preceded
350 Himalayan orogenesis and can be challenging to distinguish from Cenozoic tectonics (see
351 Gehrels et al., 2003).

352   The Eohimalayan event occurred between 50-35 Ma coincides with a dramatic decrease
353 in convergence rate between India and Asia from ∼15 to ∼4 cm/yr (Copley et al., 2010). During
354 the Miocene Neohimalayan event, the base of the GHC experienced 550-600□C and the top
355 records lower pressures and/or temperatures (3-7 kbar, 575-850□C) (e.g., Hodges et al., 1994;
356 Simpson et al., 2000; Daniel et al., 2003). The Neohimalayan event has been associated with
357 MCT slip and with the development of Miocene-age High Himalayan leucogranites found in
358 close association with STDS (Pêcher, 1989; Harris et al., 1993; Metcalfe, 1993; Hopkinson et al.,
359 2017; Liu et al., 2018; Yang et al., 2019; Wu et al. 2020).

360   The duration and onset of MCT movement varies along strike and is often attributed
361 sometime during the Miocene. To time fault activity, monazite [(Ce, La,Th)PO4] is often
362 targeted, a mineral that appears in these rocks at garnet grades and is ideal for timing
363 metamorphism (e.g., Catlos, 2013). In western Bhutan, the duration of MCT displacement is
364 bracketed by monazite ages between 20.8±1.1 and 15.0±2.4 Ma (Togbay et al., 2012). However,
365 in eastern Bhutan, prograde metamorphism and deformation is reported to have been underway
366 along the structure by c. 23 Ma (Daniel et al., 2003). Monazite ages from the lower portions of
367 the GHC in western Nepal yield younger ages timed to fault motion at 17-13 Ma (Montomoli et
368 al., 2013). Depth profiling of unpolished monazite indicate that the MCT hanging wall was
369 deforming in central Nepal between 24-22 Ma (Harrison et al., 1995). The 22 Ma age is also
370 attributed to MCT activity in central Nepal (Hodges et al., 1996; Coleman & Hodges, 1998)

371   In NW India (Garhwal region), the MCT shear zone is thought to be active from 20 Ma to
372 5 Ma (Iaccarino et al., 2020) or even younger to 1 Ma (Catlos et al., 2007; 2020). Mukhopadhyay
373 et al. (2017) suggest activity on the MCT itself in the Sikkim region occurred in pulses over an
374 extended period of time from 26 to 11 Ma. Monazite grains from the MCT shear zone in the
375 Sikkim indicate the structure was active at c. 22 Ma, 14-15 Ma, and 12-10 Ma (Catlos et al.,
376 2007) and from 21-13 Ma (Mottram et al., 2014). Younger ages are attributed to structures south
377 of the GHC-LHF contact, and are often found at lower structural levels within the shear zone
378 elsewhere. For example, Figure 5 shows the distribution of in situ secondary ion mass
379 spectrometry (SIMS) Th-Pb monazite and muscovite $^{40}Ar/^{39}Ar$ total gas ages along the Darondi
380 Khola (Catlos et al., 2001). The oldest early Miocene monazite ages are found in upper LHF
381 units (21.7±1.2 Ma to 21.1±0.8 Ma), but they decrease towards lower structural levels to 7.6±0.2
382 Ma to 6.9±0.5 Ma. In Arun valley of eastern Nepal Himalayas, Oligocene activity within the
383 upper portions of the MCT shear zone has been reported (~31 Ma, Groppo et al., 2010). Late
384 Eocene to Oligocene monazite ages have been found in GHC samples from central Nepal
385 (37.6±3.8 Ma to 30.4±0.5 Ma, Catlos et al., 2001; see also Gibson et al., 2016 for the same
386 transect) and NW India (37.9±0.9 Ma to 34.3±0.8 Ma, Catlos et al., 2007). The Oligocene ages
387 are consistent with the events related to the Eohimalayan time frame of Himalayan orogenesis
388 and may not be related to activity along the MCT.

389   Distinguishing between the Eohimalayan and Neohimalayan events is challenging, and
390 the Eohimalayan event may only be recorded in GHC and Tethyan units in particular locations
391 (Aikman et al., 2008; Stickroth et al., 2019). North-east verging folds of the Tethys Formation
392 may have developed during the Eohimalayan event (e.g., Godin et al. 1999a, 1999b), whereas
393 these and others reported in the GHC (Bhargava & Bassi, 1994; Carosi et al., 1999b) may be the
394 result of gravity sliding along the STDS (e.g., Burchfiel et al., 1992; Hodges et al., 1996; Vannay
395 & Hodges, 1996; Searle, 2010). Large-scale folding that aligns preexisting isograds into an
396 apparent inverted metamorphic position was attributed as a significant factor in the metamorphic

397 history of the GHC (Searle & Rex, 1989). In a petrochronology study of GHC monazite-bearing
398 assemblages, Gibson et al. (2016) suggest that Eocene-Oligocene monazite ages represent
399 prograde burial, which was followed by Miocene retrograde metamorphism and Miocene-
400 Pliocene exhumation. Wu et al. (2020) suggest the High Himalayan leucogranites can be
401 classified as Eohimalayan (46-25 Ma), Neohimalayan (25-14 Ma), and post-Himalayan (<14
402 Ma) based on their relationship with particular detachment systems, ages, and compositions.
403 Some North Himalayan granites that intrude Indian shelf sediments are similar in age to their
404 post-Himalayan stage (Harrison et al., 1997; 1998; Lee et al., 2004; Zhang et al., 2004).

2.2.3. Metamorphism in the LHF

406 At their base, the GHC is thrust over Middle Proterozoic phyllites, metaquartzites, and
407 mylonitic augen gneisses of LHF along the broad-scale 8-12 km thick MCT shear zone (Le Fort,
408 1975; Gansser, 1981; Arita, 1983; Brunel & Kienast, 1986; Pêcher, 1989; Searle & Rex, 1989;
409 England et al., 1992; Schelling, 1992; Le Fort, 1996; Henry et al., 1997; Harrison et al., 1998;
410 Kohn et al., 2004; Bollinger et al., 2006; Carosi et al., 2013; Parsons et al., 2016; Martin,
411 2017a,b; Mukhopadhyay et al., 2017; Yin & Harrison, 2000; Catlos et al., 2001; Catlos et al.,
412 2018; 2020). The onset of MCT activity occurred during the early Miocene (Pêcher, 1991;
413 Vannay et al., 2004; Yin, 2006), at a time when Indo-Asia convergence slows (>40% between
414 20-10 Ma, Molnar and Stock, 2009) and had a significant impact on the extrusion of the GHC
415 orogenic wedge (Maiti et al., 2020). The MCT fault system plays a central role in many models
416 for the evolution of the Himalayas (e.g., Le Fort, 1975; Searle & Rex, 1989; England et al., 1992;
417 Henry et al., 1997; Harrison et al., 1998; Bollinger et al., 2006; Kohn, 2008; Carosi et al., 2013;
418 Beaumont et al., 2001; 2004; Jamieson et al., 2004; 2006; Searle et al., 2006; Long &
419 McQuarrie, 2010; Wang et al., 2013; Cottle et al., 2015).

420 Lack of an apparent break in metamorphic grade between the GHC and LHF makes the
421 placement of the boundaries of the MCT shear zone difficult to discern. Definitions of the
422 structure center around age, metamorphic history, rheology, and role as separating units of
423 different depositional environments (see Martin, 2017a). As the GHC and LHF evolved in
424 different depositional environments, geochemical and geochronological evidence aids in its
425 placement (e.g., Parrish & Hodges, 1996; Ahmad et al., 2000; Martin, 2017a,b; Khanal et al.,
426 2014). The original Pêcher (1989) MCT definition involved three criteria in identifying the MCT
427 in the field: (1) the boundary between hanging wall gneisses and upper carbonate-rich formations
428 of the Lesser Himalaya, (2) where Lesser Himalaya shear fabric (L-S) is replaced by the
429 flattening fabric of the Greater Himalayan Crystallines, and (3) where the rotational deformation
430 that increases progressively through the Lesser Himalaya reaches a maximum. In central Nepal,
431 Arita (1983) places two thrusts (MCT-I and MCT-II) on each side of the MCT shear zone. The
432 MCT-II corresponds to that described by Pêcher (1989), whereas the MCT-I separates a
433 mylonitic augen gneiss from other Lesser Himalaya metasedimentary rocks. The MCT-I
434 correlates to the Ramgarh Thrust, which accommodates the Ramgarh Thrust sheet within the
435 LHF duplex (DeCelles et al., 2001; Robinson et al., 2003; Pearson & DeCelles, 2005; Robinson
436 et al., 2006; Matin and Mukul, 2010; Khanal et al., 2014; Mandal et al., 2015). Some researchers
437 do not recognize the MCT-I anywhere in the Nepal Himalaya (see Upreti, 1999). Along the
438 Dudh Kosi-Everest transect, the MCT corresponds to the contact between the GHC gneisses and
439 the upper LHF pelitic schists, whereas the MCT-I separates the mylonitic Phaplu augen gneiss
440 from low-grade Lesser Himalaya metasedimentary rocks. Along the Bhagirathi River, Garhwal
441 region, the Vaikrita Thrust (=MCT) and Munsiari Thrust (=MCT-I) bound the MCT shear zone,

442 but no equivalent to the Phaplu augen gneiss is exposed (e.g., Valdiya, 1980; Pêcher, 1991;
443 Metcalfe, 1993; Searle et al., 1993; Ahmad et al., 2000; Singh & Thakur, 2001).

444 The MCT footwall is characterized and defined by inverted metamorphism, where
445 metamorphic grade increases toward structurally shallower levels (e.g., Ray, 1947; Pêcher, 1989;
446 Larson et al., 2015; Chakraborty et al., 2016; Searle et al., 2008; Iaccarino et al., 2020).
447 Understanding the origin this phenomenon has implications for establishing the role of various
448 crustal heat sources and mechanisms of heat transfer within collisional belts (e.g., radiogenic,
449 asthenospheric input, shear heating, addition of melts) (e.g., England et al., 1992) and is
450 facilitated by obtaining metamorphic P-T conditions and paths from shear zone garnet-bearing
451 assemblages (Stäubli, 1989; Metcalfe, 1993; Kaneko, 1995; Vannay & Hodges, 1996; Vannay &
452 Grasemann, 1998; Manickavasagam et al., 1999; Kohn et al., 2001; Catlos et al., 2001; Imayama
453 et al., 2010; Corrie et al., 2010; Larson et al., 2013; Anczkiewicz et al., 2014; Kohn, 2014;
454 Mottram et al., 2014; Mukhopadhyay et al., 2017; Catlos et al., 2018; Waters, 2019; Catlos et al.,
455 2020).

456 The MCT has also been considered to be an expression of the Main Himalayan Thrust
457 (MHT) (Bollinger et al., 2004; Mahajan et al., 2010), a pervasive décollement that separates the
458 downgoing Indian plate from the Himalayan orogenic wedge (Figure 2) (Bilham et al., 1997;
459 Nelson et al., 1996; Subedi et al., 2018; Zhao et al., 1993). Other surface expressions of the MHT
460 include the MBT and Main Frontal Thrust (MFT) (Figure 1 and Figure 2). The STDS may be a
461 local phenomenon, occurring when the Tethys dissociated from the GHC and slid along N-
462 dipping planes due to gravity following uplift (e.g., Pêcher & Le Fort, 1986; Fuchs, 1987),
463 although some models for channel flow connect this fault system to the MHT (e.g., Beaumont et
464 al., 2001; 2004; Jamieson et al., 2004; 2006). The MHT is one of the largest and fastest slipping
465 continental megathrusts on Earth (e.g., Duputel et al., 2016; Rajendran et al., 2017; Searle et al.,
466 2017). Understanding its geometry, history, and fault systems that splay into the structure has
467 implications for assessing and predicting the initiation, propagation, and termination of major
468 event Himalayan earthquakes (e.g., Wang et al., 2017). The topography of the MHT is uncertain
469 (e.g., Caldwell et al., 2013; Denolle et al., 2015; Elliott et al., 2016; Hazarika et al., 2017;
470 Hubbard, 2016; Nábělek et al., 2009; Whipple et al., 2016; Wang et al., 2017; Zhou et al., 2019),
471 due in part to the lack of recognition that fault systems within the LHF duplex or MCT shear
472 zone have the potential to accommodate present-day slip (Catlos et al., 2020). The LHF duplex
473 has long been known to be a ~50-km-wide seismogenic zone of predominately moderate
474 earthquakes (Bai et al., 2016; Cattin & Avouac, 2000; Khattri & Tyagi, 1983; Mahajan et al.,
475 2010). Bai et al. (2016) suggest that a thrust system within the LHF is the most seismically active
476 region in the Himalayas and accommodates most of its elastic strain accumulation. Alternatively,
477 the shallower events are explained by a segmented MHT that includes a ramp (He et al., 2018;
478 Hubbard, 2016; Pandey et al., 1995).

479 **2.2.4 The MBT and MFT**

480 South of the MCT, the MBT separates the Lesser Himalaya from Neogene molasse, the
481 Siwalik Formation (Figure 1) (Valdiya, 1992; Meigs et al., 1995; Mukul, 2000; Thakur et al.,
482 2010; Goswami & Deopa, 2017; Dhamodharan et al., 2020). South of the MBT, the MFT is the
483 boundary between the Siwalik Formation and the northern Indo-Gangetic Plains (e.g., Mugnier
484 et al., 1999; Mukul et al., 2007; Burgess et al., 2012; Bollinger et al., 2014). The MBT has few
485 timing constraints, but is primarily thought to have been initiated during the Late Miocene (13-
486 10 Ma, Meigs et al., 1995; Chirouze et al., 2012; Patra & Saha, 2019), although it may have been

487 active since 5 Ma in Nepal (DeCelles et al. 2020). The Siwalik formation overall is a 7-10 km-
488 thick succession of dominantly fluvial sedimentary rocks located along the entire length of the
489 Himalaya from the Potwar plateau to the Brahmaputra in the east, likely due to the evolution of
490 the Ganga river system (Bora and Shukla, 2005; Sanyal & Sinha, 2010; Khan et al., 2019;
491 Dhamodharan et al., 2020). The Siwalik unit itself is divided into several sectors due to
492 lineaments related to normal faulting in the Indian basement that reactivated as thrust faults
493 during Himalayan collision (Raiverman et al., 1983; Dubey, 1997; Sanyal & Sinha, 2010). The
494 Siwalik formation records key information regarding Himalaya erosional history, paleoclimate,
495 transitions in paleobotany, and exhumation rates (e.g., Quade et al., 1989, 1995; Acharya, 1994;
496 Najman et al., 2009; Sanyal & Sinha, 2010; Najman et al., 2017; Ghosh et al., 2018; Khan et al.,
497 2019). In some locations, the MBT has nearby active steep faults that show normal or strike-slip
498 senses of motion as they accommodate a critical taper (Mugnier et al., 1994; Patra & Saha,
499 2019). The MFT cuts Siwalik strata in places and is often manifested as growing anticlines
500 (Yeats et al., 1992; Powers et al., 1998; Srivastava et al., 2018). These crustal-scale faults sole
501 into the MHT (Figure 2) (Zhao et al., 1993; Nelson et al., 1996).

3. Models for the extrusion of the Himalayan core

503   The MCT fault system has long played a central role in models for the evolution of the
504 Himalaya. Initial models presume that activity along the MCT only occurred during the Early
505 Miocene (Figure 6) (Le Fort, 1975; Searle & Rex, 1989; Hubbard, 1996; England et al., 1992;
506 Hodges et al., 1993; Harris & Massey, 1994). LeFort (1975) conceived that the inverted
507 metamorphism in the LHF footwall was caused by the transfer of thermal energy due to large-
508 scale underthrusting of the LHF beneath the GHC (the "Hot-Iron model" Figure 6A). In this
509 scenario, fluids released from the MCT footwall migrate through the hanging wall and flux a
510 leucogranite belt. The alternative was proposed by Hubbard (1996), in which the inverted
511 mineral isograds result from ductile shearing a pre-existing zone of right-way-up metamorphism
512 (Figure 6B). Searle and Rex (1989) delegated a significant role to STDS and suggested that the
513 present-day distribution of metamorphic facies and leucogranite bodies are caused by
514 overprinting earlier isograds during MCT-related anatexis and folding (Figure 6C). Fluids
515 released from the MCT footwall assist with the formation of leucogranite. The STDS has
516 appeared prominently in almost every model since. Hodges et al. (1993) proposed that the wedge
517 GHC extruded via synchronous STDS and MCT movement (Figure 6D), and Harris & Massey
518 (1994) suggested extensional collapse led to rapid GHC exhumation and decompression melting
519 of kyanite-bearing schists that led to melts emplaced near the STDS (Figure 6E).

520   As more data became available, more numerical solutions and quantitative models
521 appeared (Figure 7). Molnar and England (1990) matched P-T conditions obtained by Hubbard
522 (1996) by solving a one-dimensional time-dependent heat equation for an inclined fault (Figure
523 7A). The model derived thermal energy from three sources: (1) radioactive nuclides, (2) the
524 asthenosphere, and (3) frictional heating along the MCT, and suggested that shear stresses >100
525 MPa can account for peak T< 600°C at the MCT and contributes ~13°C/km to the inverted
526 geotherm. Huerta et al. (1998) introduced the idea that MCT inverted metamorphism was caused
527 by accretion and erosion acting on a crust enriched with radiogenic elements (Figure 7B). The
528 presence of post-Miocene mineral crystallization ages in the LHF and MCT shear zone led
529 Harrison et al. (1998) to model footwall inverted metamorphism as the accretion of tectonic
530 slivers of the LHF to the hanging wall (Figure 7, Figure 8A). This model was one of the first to
531 suggest the concept of critical taper as an important control in developing inverted

532 metamorphism and the geometry of the fold-and-thrust belt. In this scenario, anatexis is linked to
533 shear heating on along the MHT. This model is also the first in a series that suggested the
534 Himalaya is an outcome of stacked thrust systems within and below the GHC (Figure 8) (e.g.,
535 Kohn, 2008; Corrie & Kohn, 2011; Cottle et al., 2015; Catlos et al., 2020).

536 Large-scale imaging of the Himalayan and Tibet crust led Nelson et al. (1996) to
537 advocate that thrusting within the Himalaya results from anatexis (Figure 7D). The Tibetan
538 middle crust is assumed to be partially molten today, and the region between the MCT and STDS
539 is earlier extruded equivalent. This model is the foundation of others that suggest the GHC is the
540 result of gravity-driven lateral mid-crustal flow (Gruijic et al., 1996; Beaumont et al., 2001;
541 Jamieson et al., 2006; Searle, 2010; Webb et al., 2011; Cottle et al., 2015). Channel flow was
542 initially conceived as a Neohimalayan event, with the extrusion of the GHC due to synchronous
543 MCT and STDS activity with focused erosion along the topographic front (e.g., Beaumont et al.,
544 2001; 2004; Jamieson et al., 2004; 2006; Robinson et al., 2006; Searle et al., 2006; Long &
545 McQuarrie, 2010; Wang et al., 2013; Cottle et al., 2015). This model can be combined with the
546 scenario where LHF footwall slivers are accreted to the hanging wall as GHC channel flow
547 progressed (Figure 8B). LHF footwall inverted metamorphism may also be an outcome of
548 channel flow experienced by the GHC (Daniel et al. 2003; Searle et al., 2008).

549 Channel flow has also been invoked to model the inverted metamorphic sequence within
550 the MCT footwall, where discrete fault systems within the LHF and the MCT or other faults
551 within the GHC are active during the Miocene (Imayama et al., 2010; Goswami-Banerjee et al.,
552 2014). The alternative to channel flow is the critical taper model, where the GHC is exhumed
553 through a series of stacked thrust systems within and below the GHC (Figure 8A) (Kohn, 2008;
554 Corrie & Kohn, 2011). Critical taper has also been applied to explain thrusting with fault systems
555 associated with the MFT (Mukul et al., 2007; Hirschmiller et al., 2013). In addition, the
556 recognition that in NW India, the LHF and Tethyan Formation appear in thrust contact suggests
557 that the GHC may have acted as a tectonic wedge (Figure 8C and D) (Webb et al., 2007; Webb
558 et al., 2011; Cottle et al., 2015). One outcome of these models has been a wholesale re-
559 distribution and re-defining of the MCT from a fault system that separates the GHC and LHF to
560 one in which portions of the GHC are involved in large-scale thrust movement (Searle et al.,
561 2008; Carosi et al., 2018). The inverted metamorphic sequence is redelegated from the LHF and
562 MCT footwall to lower levels of the GHC (Figures 8E and F). Thermal heating along faults
563 within the GHC may have played a role in accommodating wedge extrusion and developing
564 inverted metamorphism (e.g., Goscombe et al., 2006; Searle et al., 2008). Figure 8G shows a
565 scenario in which the MCT shear zone develops due to imbrication and activity is accommodated
566 by fault systems within the GHC (Carosi et al., 2016). GHC structures include the Kalopani
567 shear zone (KSZ) at 41-30 Ma (Eohimalayan time frame) and High Himalayan Discontinuity
568 (HHD) at 26-24 Ma (Neohimalayan).

569 Although lines of evidence exist that the LHF inverted metamorphism involved multiple
570 episodes of post-Miocene imbrication and deformation with the MCT shear zone or LHF duplex
571 (e.g., Figure 5) (Caddick et al., 2007; Catlos et al., 2001; Kohn et al., 2001; Groppo et al., 2009;
572 2010; Herman et al., 2010; Mosca et al., 2012; Montomoli et al., 2013; Mottram et al., 2014;
573 Carosi et al., 2016; Braden et al., 2018; Catlos et al., 2018; Montemagni et al., 2018; Catlos et
574 al., 2020; Montemagni et al., 2020), the idea of tectonic inversion of a coherent rock package
575 that experienced a single Barrovian Neohimalayan-related metamorphic event remains (Hubbard,
576 1996; Martin et al., 2010; Gaidies et al., 2015). Multiple episodes of ductile overthrusting of the

577 GHC over the LHF are proposed as an explanation (Goscombe & Hand, 2000), as well as post
578 and tectonic overpressure that changed fundamental rock properties (Thakur et al., 2015; model
579 of Schmalholz & Podladchikov, 2013). The originally-proposed "hot iron" model in which the
580 primary heat source for inverted metamorphism is GHC thermal energy transferred as Miocene
581 MCT emplacement occurred (England & Molnar, 1993) has an alternative end-member, where
582 no contribution of dissipative to downward conductive heating from the GHC is required
583 (Stephenson et al., 2000).

584 The Himalaya is often framed as a large-hot orogen that may have grown by distributed
585 extrusion (channel flow) or discrete thrusting (critical taper) (Beaumont et al., 2006; Jamieson &
586 Beaumont, 2013; Mukherjee, 2013; Iaccarino et al., 2020; review in Wang et al., 2013). In fact,
587 both scenarios may be relevant to the Himalayan core, depending on the location within the
588 range and the time frame of metamorphism (Larson et al., 2010; Mukherjee, 2013; Cottle et al.,
589 2015). The Himalaya may indeed represent a scenario in which the two 'end-member models
590 apply and are not mutually exclusive (Beaumont & Jamieson, 2010; Larson et al., 2010, 2013;
591 Corrie et al., 2012; Jamieson & Beaumont 2013; Cottle et al., 2015). Evaluating models for GHC
592 extrusion requires understanding of the P-T-t paths of its rocks as they experienced the transition
593 from convergence and subduction to their final exhumation (e.g., Catlos et al., 2001; Caddick et
594 al., 2007; Kohn, 2008; Corrie et al., 2010; Goswami-Banerjee et al., 2014; Catlos et al., 2018,
595 2020).

596 Kohn (2008) presents particle paths predicted by end-member critical taper and channel
597 flow models in the end-member models. Channel flow predicts the GHC experienced isothermal
598 exhumation, and the LHF experiences isobaric heating. Critical taper predictions imply isobaric
599 cooling for GHC rocks and "hair-pin" LHF P-T paths (Kohn, 2008). The metamorphic field
600 gradients predicted by the models also differ. Complicating this scenario is the observation that
601 P-T conditions from garnet-bearing assemblages collected from the MCT hanging wall indicate
602 the unit has cryptic discontinuities related to unmapped faults, shear zones, or inheritance of pre-
603 existing basement structures (see discussions in Mukherjee et al., 2012; Larson et al., 2013;
604 Montomoli et al., 2015; Cottle et al., 2015; Carosi et al., 2016). Understanding when these
605 possible fault systems, termed High Himalayan discontinuities (HHD), were active is critical for
606 deciphering the processes involved during convergence. Their age may similar to activity along
607 the MCT (28-18 Ma; e.g., Carosi et al., 2010; Montomoli et al., 2013, Larson et al., 2015;
608 Montomoli et al., 2015; Carosi et al., 2016; Carosi et al., 2018; Benetti et al., 2021). This is a
609 scenario that is not accounted for in the channel flow model (e.g., Benetti et al., 2021; Maiti &
610 Mandal, 2021).

4 Himalayan Metamorphism and Contractional Tectonics (Darondi Khola, Central Nepal)

611

612 As indicated in the previous sections, garnet-bearing assemblages are valuable recorders
613 of compressional/contractional metamorphism and help constrain models for the Himalaya's
614 uplift history. P-T data from garnet-bearing Himalayan assemblages can be generated using
615 several approaches (see review in Waters, 2019). This section compares conditions generated
616 using conventional thermobarometers and the Gibb's method (Kohn et al., 2001) to those
617 obtained using isochemical phase diagrams, isopleth thermobarometry, and the garnet zoning
618 method (e.g., de Capitani & Petrakakis, 2010; Moynihan & Pattison, 2013; Catlos et al., 2018;
619 2020). The approaches were applied to the same samples and data from rocks collected from the
620 GHC and LHF units along the Darondi Khola in central Nepal (Figure 3, Figure 4, Figure 5). The
621 TheriaG model of Gaides et al. (2008) is also used to predict garnet zoning based on Gibb's P-T

622 paths for some samples. The reason for any discrepancies in the P-T paths and conditions within
623 the context of equilibrium thermodynamics is evaluated, and the impact of the results on models
624 for Himalayan orogenesis is explored. Regardless of calibrations used, the P-T conditions and
625 paths coupled with previously-reported timing constraints from Darondi Khola assemblages
626 suggest the MCT shear zone developed during pulses of movement that resulted in progressive
627 transfer of rock packages as the MCT shear zone developed (Catlos et al., 2001; Kohn et al.,
628 2001).

629 **4.1 Methods, samples, and assumptions**

630 **4.1.1 Samples**

631   Kohn et al. (2001) report rim P-T conditions from eighteen garnet-bearing assemblages
632 exposed along the Darondi Khola and divides LHF samples into lowermost (n=3), lower to mid
633 (n=6), and upper MCT zones (n=4) (Figure 4 and Figure 5, Table 1). Five GHC rocks were also
634 analyzed. We use the definition of the MCT shear zone following this nomenclature, but also
635 note that based on the placement of the Phaplu and Ulleri augen gneisses, others would allocate
636 all of these samples squarely in the GHC unit (e.g., Searle et al., 2008).

637   Mineral assemblages, X-ray element maps, and compositional transects were made across
638 garnets and are reported in Kohn et al. (2001). Petrographic images of some samples are shown
639 in Figure 9. All samples contain garnet and prograde quartz, muscovite, biotite, and ilmenite. All
640 are metamorphosed pelites, except DH38, which is a metabasite and contains hornblende and
641 plagioclase. All lower LHF rocks contain prograde chlorite and plagioclase, but DH75A and
642 DH75B also have retrograde chlorite (Figure 9). The upper LHF and GHC rocks do not have
643 chlorite (DH38, DH60, DH61, DH63, DH66, DH67) or contain only retrograde chlorite (DH57,
644 DH58, DH71). All samples, except upper LHF rock DH57, contain plagioclase. Most plagioclase
645 show core-rim zoning with higher-Ca cores and lower-Ca rims, expected if garnet grew in a
646 closed chemical system (Spear et al., 1990). Samples DH26, DH75A, and DH75B have
647 plagioclase with relict albite cores overgrown by an oligoclase mantle that is either unzoned or
648 slightly zoned to lower Ca towards its rim. The mantle was assumed to be metamorphic and
649 reflects garnet growth and uptake of Ca. Sample DH57 has both staurolite and kyanite, whereas
650 DH63 has staurolite. Other rocks for this study do not show any of these index minerals. No
651 chloritoid or carbonate minerals are reported in the samples. All samples appear syntectonic and
652 the presence of strain shadows are common. As seen in Figure 9, micas and quartz appear
653 deflected around the garnet porphyroblasts. Some garnets are inclusion free, however, middle
654 LHF sample DH30 has quartz inclusions in the center of the garnet that appear thinner and
655 elongated compared to the larger, anhedral grains in its outer-rim region. GHC samples DH61,
656 DH63, and DH67 have inclusion filled cores and inclusion free outer rims. Inclusions of ilmenite
657 and quartz in middle LHF samples DH51 and DH75B are aligned in relatively straight tracks
658 into the rock matrix, consistent with syntectonic growth.

659   Figure 10 shows garnet compositional transects for LHF samples in which high-
660 resolution P-T paths (DH17, DH19, DH22, DH23, DH26, DH75B) were obtained and Figure 11
661 shows compositional transects across garnets in two GHC samples (DH61 and DH66). LHF
662 samples show typical prograde bell-shaped profiles in Mn, with no evidence of retrogression at
663 the rims. The garnets all show a smooth decrease in grossular and increase in pyrope and
664 almandine from core to rim. GHC garnets, however, show evidence of retrogression with sharp
665 increases in Mn contents at the rim. These garnets also show significant fluctuations in grossular,

666 pyrope, and almandine from core to rim. GHC samples are not ideal candidates for high-
667 resolution P-T path modeling because their zoning profiles suggests modification of prograde
668 garnet compositions after growth, open-system behavior, and the potential of major changes in
669 rock bulk composition after growth. These situations are assumed not to occur when modeling
670 and developing high-resolution P-T paths.

4.1.2 Conventional thermobarometry and Gibbs method P-T paths

672 The garnet-biotite thermometer calibrated by Ferry and Spear (1978) with the Berman
673 (1990) Ca-in garnet solution model and the garnet-muscovite-biotite-plagioclase barometer of
674 Hoisch (1990) were applied to the assemblages with pelitic bulk compositions (Kohn et al.,
675 2001). Sample DH38 is a metabasite, so the garnet-hornblende thermometer of Graham and
676 Powell (1984) and the garnet amphibolite barometer of Kohn & Spear (1990) were used. Results
677 are summarized in Table 1. The conditions are internally consistent, and Kohn et al. (2001)
678 emphasize that different calibrations would change estimated P and T by $\pm 25°C$ and ± 0.5–1 kbar
679 and would not alter overall trends. The conditions were estimated using minimum garnet Mn
680 contents. Note that these garnet compositions are the same used for the estimating the garnet rim
681 conditions using isopleth thermobarometry as described in the next section (Table 2; polygons in
682 Figure 12, Figure 13, Figure 14, Figure 15, Figure 16, Figure 17).

683 The Gibb's method to generate the P-T paths from zoned garnets and their co-existing
684 matrix mineral assemblages is outlined in Spear & Selverstone (1983), Spear (1986, 1993), Spear
685 et al. (1984), and Spear & Rumple (1986). P-T paths were only generated from LHF rocks with
686 pelitic bulk compositions (DH16, DH17, DH22, DH23, DH26, DH75A, and DH75B) that
687 preserved prograde compositional zoning best. The rocks were modeled with the observed solid
688 assemblage garnet + biotite + chlorite + muscovite + plagioclase + quartz in the
689 MnNCKFMASH system. Compositional changes were derived from garnet and plagioclase
690 compositional zoning produced as the garnet grew. Garnet core and rim conditions were selected
691 for samples DH17, DH19, DH22, and DH26, whereas an intermediate point was also included
692 for samples DH23, DH75A, and DH75B. This intermediate garnet composition was used to
693 better account for nonlinearity in the garnet zoning pattern. In the case of DH23 and DH75B, its
694 inclusion results in hair-pin P-T paths (Figure 13A, Figure 14C, and Figure 17). A pure H2O
695 fluid at lithostatic pressure was assumed to have been present. Kohn et al. (2001) emphasize that
696 activity models would not significantly affect the trends of retrieved P-T paths.

697 The P-T results obtained using conventional and Gibb's method show an inverted
698 metamorphic signature in the LHF, with P-T conditions increasing up section from near the
699 garnet isograd at $520\pm 25°C$ and 5.0 ± 1.0 kbar (DH16) to $640\pm 25°C$ and 11.5 ± 2 kbar (samples
700 DH57 and DH58) just below the mapped MCT. GHC rocks were collected near the mapped
701 MCT (Figure 4 and Figure 5) and record the highest P-T conditions (660-715°C and 7.6-11.5
702 kbar). Samples DH17, DH19, and DH75A have P-T paths consistent with burial (increasing in
703 both P and T), whereas those from DH22 and DH26 yield exhumation paths (decreasing P with
704 increasing T). P-T paths from DH75B and DH23 are "hair-pin" and are interpreted as recording
705 both burial and exhumation during imbrication of the MCT shear zone. Monazite inclusions in
706 DH75B garnets range from 11.1 ± 0.7 Ma to 7.6 ± 0.2 Ma (Th-Pb secondary ion mass
707 spectrometry, SIMS, $\pm 1\square$) and were interpreted as constraining Late Miocene reactivation of the
708 MCT shear zone (Figure 5). These Late Miocene monazite inclusions in garnet are also found in
709 other samples along the transect as well as young (Pliocene-Late Miocene) $^{40}Ar/^{39}Ar$ muscovite
710 total gas ages (Catlos et al., 2001; Kohn et al., 2001).

4.1.3 Isopleth core thermobarometry

711

712   The approach to obtain isopleth P-T conditions and paths is the same as that outlined in
713   Catlos et al. (2018, 2020) and Etzel et al. (2019). Bulk rock compositions were obtained from
714   rock chips of the DH samples using inductively coupled plasma spectrometry (ICP) at Activation
715   Laboratories (Canada) (Table 3 and Table 4). No modifications in these compositions were made
716   for the approach. Samples DH22 and DH23 were collected nearby, and the same bulk
717   composition is used for both rocks. Compositions vary from low SiO_2 (~45 wt % samples DH17,
718   DH22, and DH23) to higher SiO_2 (69-76 wt% DH26, DH75A). In general, upper LHF and GHC
719   rocks have mid to high SiO_2 contents (56-80 wt%). Their molar values are used as direct input
720   for the effective bulk composition needed to create the isochemical phase diagrams using the
721   software package Theriak-Domino (de Capitani and Brown, 1987; de Capitani and Petrakakis,
722   2010) (Figure 12, Figure 13, Figure 14, Figure 15, Figure 16, Figure 17). The Holland and
723   Powell (1998 with updates to solution models through 2010) thermodynamic dataset and
724   appropriate mixing models in the system $MnO-Na_2O-CaO-K_2O-FeO-MgO-Al_2O_3-SiO_2-H_2O-$
725   TiO_2 were used. The specific solid solution models used are the same as in Catlos et al. (2018).
726   H2O saturation is assumed for these samples (i.e., H2O (100) in Theriak Domino), as is
727   appropriate for these assemblages. Fe^{3+} was not estimated but did not significantly affect results.

728   For samples where compositional data were available from the garnet's central section,
729   isopleths of ±0.01-0.02 mole fraction spessartine, almandine, pyrope, grossular, and ±0.01-0.02
730   Mg-# (Mg/Fe+Mg), are plotted on the phase diagram as grey-shaded bars. Their intersection
731   corresponds with our closest approximation of garnet core P-T conditions as indicated by a
732   polygon. Although isopleth intersections occurred over small regions, the uncertainty in the
733   conditions is likely approaching that of conventional methods (i.e., ±25°C and ±1 kbar).
734   Overlapping garnet core isopleths are only found for LHF samples DH17, DH19, DH22, DH23,
735   DH26, DH75A, DH75B, DH58, and GHC sample DH61 (Figures12, Figure 13, Figure 14,
736   Figure 15, Figure 16). The core was defined as the portion of the garnet with the highest Mn
737   content and is the best approximation of the chemical system when garnet began growth. In all
738   cases, the intersections are located in mineral stability fields consistent with their assemblages
739   (feldspar + garnet + biotite + phengite + ilmenite ± rutile ± chlorite + quartz + H2O) and
740   anticipated conditions. Core metamorphic conditions increase up section over a north-south
741   distance of ~5 km from a low of 4-4.5 kbar and 520-540°C in lower LHF samples DH17 and
742   DH19 to 6.8-7.5 kbar and 540-550°C in middle LHF samples DH75A and DH75B (Table 2).
743   Upper LHF sample DH58 collected directly beneath the MCT yields overlapping core isopleths
744   at ~550°C and 6.0 kbar. Core isopleths for GHC sample DH61 overlap at ~7 kbar and 580°C,
745   similar to those from some LHF rocks (Table 2).

746   The garnet-in reaction line and garnet growth contours (volume 0.5% increments) are
747   overlaid on each isochemical phase diagram (Figure 12, Figure 13, Figure 14, Figure 15, Figure
748   16). The topology of the diagrams and the location of the garnet core suggest that garnet appears
749   in all samples through chlorite dehydration. Only samples DH75A and DH75B yield core P-T
750   conditions that overlap the garnet-in reaction line (Figure 14). The other samples yield
751   overlapping isopleths on or near the 0.5% (DH17, Figure 12A), 1% (DH19, DH61, DH58, Figure
752   12C, Figure 15A and Figure 15C), and 1.5-2% volume contours (DH22 and DH23, Figures 12E
753   and Figure 13A). The results suggest that the true core was missed during the analysis of these
754   garnets. The lack of retrograde zoning in the LHF samples suggests that the effect of diffusional

755 homogenization is minimal (Figure 10), although this process likely modified GHC DH61 garnet
756 compositions (Figure 11B).

4.1.4 High-resolution and Gibb's P-T path modeling

758   For samples DH17, DH19, DH22, DH23, DH26, DH75A, and DH75B, the garnet's core
759 isopleth P-T conditions can be directly compared to those obtained using the Gibb's approach
760 (Figure 17). Sample DH26 yields the same pressure using both methods (~6.5 kbar), but the
761 thermal conditions are lower using the Gibb's method by 50°C. Sample DH23 yields the same
762 thermal conditions using both approaches (~525°C), but the isopleth barometry suggests the
763 sample experienced lower pressures by ~2 kbar (5.1 kbar compared to 7.0 kbar). In all other
764 samples, isopleth thermobarometry results in the samples recording lower P (from 0.5 kbar to 1.7
765 kbar, samples DH75A and DH75B) and higher T (from 10°C to 50°C, samples DH75A and
766 DH75B) compared to than those generated by the Gibb's method. The discrepancies of 10°C and
767 0.5 kbar are within the stated uncertainties of both methods (Kohn, 1993), but those approaching
768 50°C and 1.5 kbar are significant differences that would influence understanding their depth of
769 exhumation and metamorphic reaction history. For example, in sample DH26, the Gibb's core P-
770 T condition shows similar P, but the low Gibb's T starting conditions lie in a region where
771 chlorite, not garnet, is stable (Figure 13C).

772   High-resolution P-T paths (Moynihan and Pattison, 2013) were generated for lower LHF
773 samples where garnet transect data were available, suggested prograde conditions, and minimal
774 modification since growth. In generating the high-resolution P-T paths, zoning profiles are
775 smoothed using a Savitzky-Golay function to minimize the impact of missing analyses due to
776 inclusions or cracks (Figure 10). The Matlab script starts with the bulk composition and initial
777 smoothed core garnet composition and calls Theriak-Domino to calculate an isochemical phase
778 diagram. A Matlab optimization function searches the P-T grid for the smallest misfit between a
779 modeled garnet composition and the smoothed composition. It then calculates the portion of the
780 bulk composition sequestered in the first step of garnet growth. Sequestered components are
781 subtracted from the bulk composition to estimate an effective bulk composition for the next step
782 of growth. A new diagram is calculated from the effective bulk composition, and the process is
783 repeated for all steps along the garnet zoning profile from core to rim. Each step yields an
784 estimate of the P-T conditions of incremental garnet growth, culminating in a P-T path. This data
785 is available in the repository.

786   Two independently estimated high-resolution P-T paths can be obtained from a rim-to-
787 rim compositional transect across the garnet using the garnet zoning method. The expectation is
788 that the P-T paths from the same garnet should record similar trajectories, and was the case for
789 samples DH17, DH19, and DH23 (Figures 12A and C, Figure 13A). The starting and endpoints
790 may differ due to the proximity of the initial condition near the garnet core and the extent of
791 garnet rim preservation. In addition, garnet zoning can be predicted by the high-resolution P-T
792 path and is indicated as a bolder grey line in Figure 10. The high-resolution P-T paths reproduce
793 the original garnet zoning to ±0.01 mole fraction in most cases and for most compositions, which
794 is expected if the garnet behaved in a closed system and had no significant changes in bulk rock
795 composition as it grew.

796   As with the core conditions, the shapes of the high-resolution P-T paths for samples
797 DH17, DH19, DH22, DH23, DH75A, and DH75B can be directly compared to those obtained
798 using the Gibb's approach (Figure 17). The length of the high-resolution and Gibb's P-T paths are

799 similar (ranges from 14°C to 52°C) but do not show the same trajectories. For example, instead
800 of hair-pin trajectories (increase in P followed a P decrease as T increases) predicted by DH23
801 and DH75B Gibb's P-T paths, their high resolution P-T paths suggest that these rocks only
802 experience an increase in P as T increased. The Gibb's P-T path in sample DH17 shows an
803 increase in P, but the high-resolution P-T path from the same rock using the same data decreases
804 in P as T increases. Minor fluctuations in P in the high-resolution P-T paths (±10-50 bars) in
805 sample DH19 and near the core of sample DH22 are likely due to small compositional changes
806 as the program seeks the best fit and should not be interpreted tectonically. DH19 shows an
807 overall similar P-T path shape as the one reported using the Gibb's approach, but the conditions
808 are different with the high-resolution P-T path showing much lower P (by ~2 kbar) and higher T
809 (by ~50°C). The high-resolution P-T paths from samples DH22 and DH23 are similar in that
810 they show minor increases in P as T increased, but the Gibb's P-T path from sample DH22
811 suggests decompression, a result not observed with this sample. A P-T path from sample DH26
812 could not be generated due to a lack of garnet zoning data, but core and rim isopleth conditions
813 suggest it could have followed the decompression path as T increased. A decrease in P as T
814 increased is the same trajectory suggested by the Gibb's P-T path but at higher T conditions.

815 To gauge how well Gibb's P-T paths reproduce garnet zoning, the Gibb's P-T path was
816 used as input in the program TheriaG (Gaides et al., 2008) using the bulk composition indicated
817 in Table 3. The time of garnet growth over the P-T path is regularly spaced over durations of 5
818 m.y., 10 m.y., and 15 m.y. Modeling parameters are available in supplementary files. In each
819 case, the predicted Gibb's P-T path was identical and would predict garnet zoning inconsistent
820 with what is observed in the sample (Figure 10). Results may change if different size classes than
821 those used were selected (10 μm successive shells in 2000 ☐m garnet radius), if garnet growth
822 did not occur over regular space durations, or if the selected exhumation path was different.
823 Using the chosen parameters, the Gibb's P-T path predictions for samples DH17, DH19, and
824 DH22 show similar trends with the garnet zoning but significantly different compositions (Figure
825 10). The Gibb's P-T paths predictions for those samples that produced hair-pin P-T paths
826 (DH75B and DH23) resulted in significantly different garnet zoning and compositions and did
827 not replicate observed garnet compositions.

828 **4.1.5 Isopleth rim thermobarometry**

829 Garnet rim isopleth conditions were estimated using the same garnet compositions used
830 to generate conventional P-T conditions. Rim isopleths also include those from the sample's
831 average composition of matrix plagioclase (±0.01 mole fraction Ca), chlorite, and biotite [±0.01
832 Mg-number, Mg#= Mg/(Mg+Fe)], when available. The last effective bulk composition generated
833 by the high-resolution P-T paths was used for LHF samples DH17, DH19, DH22, DH23, and
834 DH75B. For other LHF samples where garnet transect data is not available and for the GHC
835 rocks, the bulk composition was used (DH26, DH75A, DH58, DH60, DH61, DH63, DH66,
836 DH67) (Table 3 and Table 4). Only three GHC samples (DH61, DH63, and DH66) yield
837 overlapping garnet compositional isopleths (Figure 15D, Figure 16A and B), and those from
838 upper LHF sample DH58 did not overlap.

839 The extent of overlap of garnet rim with matrix mineral compositions varies for the GHC
840 and LHF rocks. Garnet rim isopleths for GHC sample DH61 rim overlapped with all matrix
841 mineral compositions, but DH66 show no overlap of the garnet rim with any of the matrix
842 mineral compositions. The garnet rim isopleths for GHC sample DH63 overlapped with ±0.01
843 Mg-number chlorite, but not with the biotite or plagioclase compositions. As seen with some

844 footwall samples, the overlaps for the GHC assemblages are located far from the garnet-in
845 reaction line as seen by the garnet growth contours (>1.5 vol%) (Figure 15 and Figure 16). The
846 garnet rim isopleths for LHF samples DH17, DH19, DH22, DH23, and DH75B overlap with
847 Mg# biotite, but not plagioclase. No matrix mineral isopleths overlap with the garnet rim
848 isopleths for samples DH26 and DH75A within the compositional ranges applied here (±0.01
849 mole fraction Ca and Mg#).

850   For samples where garnet and matrix mineral isopleths overlap, conditions are consistent
851 with their mineral assemblages and are similar to the garnet core assemblages (feldspar + garnet
852 + biotite + phengite + ilmenite ± rutile ± chlorite + quartz + H_2O). As with the core conditions,
853 the rim P-T conditions increase up section over a north-south distance of ~5 km from a low of
854 4.5-4.8 kbar and 550-560°C in lower LHF samples DH17 and DH19 to 5.5-8.8 kbar and 560-
855 590°C in middle LHF samples (Table 2). Although garnet compositional data is not available for
856 Upper LHF sample DH51, its mineral assemblage of coexisting staurolite and kyanite allows for
857 an approximation of rock conditions using only its bulk rock composition and observations
858 conditions where these mineral coexist (Figure 15E), which appears at ~7.0 kbar and ~650°C.
859 Rim isopleths for GHC samples DH60, DH61, and DH66 yield similar P of ~7 kbar, but T
860 ranges from 550-600°C. GHC sample DH63 yields the highest P-T isopleth conditions of ~10.5
861 kbar and 650°C.

862   Comparisons are made between the conventional rim P-T conditions and isopleth rim
863 conditions. As seen in Figure 17B, the lower LHF samples yield higher T (by 25-30°C) and
864 lower P (by 1.4-2.3 kbar). All middle LHF samples (Figure 17D and F) overlap in P conditions
865 within uncertainty, but the isopleth T for samples DH22 and DH26 is higher than the
866 conventional results by 5-85°C, depending on how uncertainty is applied. For GHC sample
867 DH61, the approaches yield similar T conditions, but P differ by 1-2 kbar, depending on
868 uncertainty (Figure 17F). The opposite observation is seen with GHC sample DH66, where P is
869 similar, but the isopleth conditions suggest significantly lower T (Figure 17F). Some overlap is
870 seen with GHC sample DH63, but the conventional results suggest higher P-T than the isopleth
871 results.

5 Discussion

873   Using the same samples and data, Darondi Khola MCT footwall P-T paths using the
874 Gibb's method and high-resolution garnet modeling do not yield the same conditions or shapes
875 (Figure 17), even within the estimated uncertainties of the Gibb's method (e.g., Kohn, 1993). In
876 addition, the lowest-grade footwall samples record higher T and lower P isopleth rim P-T
877 conditions than those generated using conventional thermometers and barometers. Conventional
878 garnet rim P-T conditions and isopleth thermobarometry for GHC samples yield absolute
879 conditions that differ, although overlap exists within uncertainty (±25°C and ±1kbar). An
880 important check on the feasibility of the P-T conditions generated using any approach is if the
881 results seem geologically reasonable and consistent with mineral assemblages (e.g., Moynihan
882 and Pattison, 2013; Kelly et al., 2015; Catlos et al., 2018; Etzel et al., 2019; Craddock Affinati et
883 al., 2020). However, this is the case with all conditions reported for the Darondi Khola samples,
884 regardless of approach.

885   Several assumptions underlie many P-T estimates generated using thermodynamic
886 modeling. For all thermobarometric methods applied here, a critical assumption is that the
887 minerals in a sample experienced equilibrium, which can never be proven for any rock system

888 (e.g., Spear & Peacock, 1989; Lanari & Duesterhoeft, 2019). The samples are also assumed to
889 have experienced closed system behavior, and the original compositions of the mineral phases
890 and the bulk rock have not changed significantly since metamorphism (e.g., Lanari and Engi,
891 2017). LHF assemblages appear to have preserved their original garnet compositions, as shown
892 by their prograde zoning profiles (Figure 10). Garnets with preserved divalent cation zoning
893 based on previously reported thermal conditions of generally <600°C (e.g., Carlson, 1989, Spear,
894 1993; Carlson 2002), consistent with the results shown here. GHC samples show fluctuations in
895 garnet compositions from core to rim and have evidence of diffusional modification by an
896 increase of Mn at the rims (Figure 11).

897 Multiple sources of error are inherent in conventional P-T conditions and include
898 uncertainty in the accuracy of end-member reactions, electron microprobe analyses, calibration
899 errors, variations in activity models, and compositional heterogeneity (e.g., Kohn & Spear,
900 1991). The precise uncertainty with approaches that involve isochemical phase diagrams is
901 likewise challenging to determine due to the same factors incorporated into their creation as well
902 as uncertainty associated with the thermodynamic properties inherent in the choice of internally
903 consistent database (e.g., molar enthalpy of formation, molar entropy, molar volume, heat
904 capacity, bulk modulus, Landau parameters, and Margules parameters, e.g., White et al., 2014;
905 Lanari & Duesterhoeft, 2019). The error suggested by the grid created due to overlapping
906 mineral compositional isopleths likely underestimates the actual uncertainty in the identified
907 conditions. Applying a standard values of uncertainty (±25°C and ±1 kbar) to the overlapping
908 isopleth conditions as those used for conventional results appears appropriate, and is commonly
909 reported (e.g., Spear & Peacock, 1989; Kohn, 1993; Kohn et al., 2001).

910 Ultimately, each approach to generating P-T conditions discussed here transforms the
911 sample into a model representing the true rock and mineral assemblage but restricts its behavior
912 as if it was in a closed system that experienced particular boundary conditions. Confidence in
913 conventional and Gibb's P-T paths increases when conditions agree with minerals assemblages
914 and if the P-T paths reproduce broad-scale trends in garnet zoning from core to rim. Samples
915 collected from the same outcrop or nearby should yield similar P-T conditions and paths.
916 Although Kohn et al. (2001) only report one Gibb's P-T path per sample, the expectation is that
917 multiple paths collected from the same garnet or multiple garnets in the same rock would agree
918 in terms of shapes and conditions. The high-resolution P-T path approach and the garnet isopleth
919 thermobarometry use these same criteria to evaluate the estimated result's appropriateness.
920 However, they have two additional values in critically evaluating results. First, a user can gauge
921 the extent of overlapping mineral isopleths in P-T space. Second, a user can identify how well
922 the high-resolution P-T paths predict the trends and values of garnet compositional zoning
923 (Figure 10). A significant value of the high-resolution P-T path and isopleth approaches is that a
924 user can detect when systems stray from the equilibrium and closed system assumptions.

925 These samples illustrate that not all garnets are suitable candidates for high-resolution P-
926 T path modeling and isopleth thermobarometry. Garnets with significant changes in composition
927 over short distances from core to the rim and those affected by diffusion cannot be modeled.
928 Garnets in samples that experienced significant changes in bulk composition or multiple
929 deformation episodes resulting in modification of composition are also unable to be modeled.
930 Not all field areas are ideal candidates, and the GHC samples show that they often fail
931 assumptions required for isopleth thermobarometry and high-resolution P-T path modeling. For
932 example, overlapping garnet core isopleths were only found for one GHC sample DH61, and this

933   was located far from the garnet-in reaction line (Figure 15C). In fact, the intersections for all
934   samples, except DH75A and DH75B, are far from the garnet-in reaction line (>1 vol%), although
935   all overlap mineral stability fields consistent with rock assemblages. The compositional core may
936   not coincide with the geometric garnet center (e.g., Spear & Daniel, 1998), shown for most
937   samples. Overlapping garnet compositional rim isopleths were found for three GHC samples
938   (DH61, DH63, DH66), but only GHC sample DH61 appears ideal as garnet rim isopleths also
939   intersect those of the matrix minerals (±0.01 mole fraction Ca in anorthite and ±0.01 Mg#
940   chlorite and biotite). Confidence in isopleth conditions increases when matrix mineral
941   compositions overlap the garnet rim conditions, as these mineral compositions are independent.

942   The high-resolution P-T paths should be considered approximations of how a garnet with
943   a specific type of compositional zoning would behave in a closed system of a known bulk
944   composition as it evolves during increasing T. Rocks are open systems, but LHF garnet-bearing
945   assemblages appear as if they approach an ideal scenario of a closed system. This appearance of
946   equilibrium is shown by overlapping isopleths of compositions from the garnet core and from
947   those of the garnet rim with matrix minerals. In addition, predictions of garnet zoning made by
948   the high-resolution P-T paths closely match the original garnet for these samples (Figure 10).
949   Multiple paths from the same sample yield similar conditions and shapes. The inability to
950   reproduce garnet zoning using Gibb's P-T path trajectories using TheriaG modeling suggests
951   these paths may not be relevant to the samples using the applied parameters.

952   Regardless of calibrations used, the P-T conditions and paths along with previously-
953   reported timing constraints, are consistent with an imbrication model that suggest the MCT shear
954   zone developed as rock packages within the LHF were progressively transferred (Catlos et al.,
955   2001; Kohn et al., 2001). For example, Figure 18 shows P-T path predictions for one such
956   imbrication model described in Catlos et al. (2018) and (2020). In this model, thermobarometric
957   histories are calculated using a two-dimensional finite-difference solution to the diffusion-
958   advection equation. Samples within the LHF travel along the MCT at a 5 km/Ma speed rate from
959   25 to 18 Ma (Figure 18A). The hanging wall speed rate is 10 km/Ma, and topography
960   progressively accumulates until a maximum height of 3.5 km. The increase in topography is
961   required to accommodate the pressure changes recorded by the garnets while matching their
962   thermal histories. Once the topography is achieved at 18 Ma, a period of cessation is applied to
963   the MCT between 18 and 15 Ma, and topography is reduced at a rate of 1.5 km/Ma. The model
964   returns to activity within the MCT shear zone with the activation of the MCT footwall slivers
965   from 8 to 2 Ma (Figure 18B). P-T changes recorded by the footwall garnets are the direct result
966   of thermal advection combined with alterations in topography. Changes in the timing of fault
967   motion would affect the model outcomes. However, the model's current constraints and
968   boundary conditions appear to match the observed high-resolution P-T paths. For example, the
969   P-T diagram in Figure 18 C-E are model predictions for samples that experienced imbrication in
970   the MCT footwall. High-resolution P-T paths are also plotted in these panels from samples
971   collected from the LHF along the Darondi (Figure 18C) and Marsyangdi (Figure 18D) rivers in
972   central Nepal and from along the Bhagirathi River in NW India (Figure 18E). For most samples,
973   the P-T paths match the model predictions remarkably well. P-T paths for sample DH75B (Panel
974   18C) suggests the possibility of very high exhumation rates (>12mm/year) within the MCT shear
975   zone since the Pliocene, which is a scenario predicted by this imbrication model.

976   **6 Conclusions**

977   This paper reviews the geological framework of the Himalayas and describes and applies
978   particular thermobarometric approaches to decipher the metamorphic history of garnet-bearing
979   rocks collected across the MCT along the Darondi Khola in central Nepal using previously
980   reported data (Kohn et al., 2001). A comparison is made between the results of conventional and
981   isopleth thermobarometry for all samples and high-resolution and Gibb's P-T paths for MCT
982   footwall rocks only. A significant value of the high-resolution P-T path and isopleth approaches
983   is that a user can detect when systems stray from the equilibrium assumption. Confidence in
984   conditions exists when minerals assemblages predicted by thermodynamic modeling appear
985   consistent with the actual rock and when the P-T paths reproduce broad-scale trends in garnet
986   zoning from core to rim. The expectation is that multiple paths collected from the same garnet or
987   multiple garnets in the same rock would agree in terms of shapes and conditions and that samples
988   collected from the same outcrop or nearby should record similar P-T conditions and paths. Using
989   isopleth thermobarometry, a user can gauge the extent of overlapping mineral compositions and
990   where the overlap occurs with respect to the garnet-in reaction line and garnet volume % growth
991   contours. MCT footwall garnet compositions predicted by Gibb's P-T paths using the software
992   package TheriaG fail to reproduce the original garnet zoning. However, high-resolution P-T
993   paths reproduce the original garnet zoning to ±0.01 mole fraction in most cases and for most
994   compositions, expected if the garnet behaved in a closed system and had no significant changes
995   in bulk rock composition as it grew. Although the assumption of equilibrium has long been
996   known can never be proven for any rock system (e.g., Spear & Peacock, 1989), isopleth
997   thermobarometry and high-resolution P-T path modeling applied to garnet-grade Himalayan
998   MCT footwall assemblages show they appear to behave as if they evolved in a closed system that
999   experienced particular P-T path trajectories. Ultimately, the P-T conditions and paths generated
1000   for rocks across the MCT along the Darondi Khola, regardless of calibrations used, are consistent
1001   with the imbrication model that suggest the MCT shear zone developed as rock packages within
1002   the LHF were progressively transferred (Catlos et al., 2001; Kohn et al., 2001).

A "*" indicates an incipient fault. (D) Illustration of GHC tectonic wedging after Webb et al. (2011). Panels (E) and (F) show the final geometry of the range, which has affected the position and definition of the MCT. Panels (A), (B), (C), and (E) are after Cottle et al. (2015), and panel (F) is after Searle et al. (2008).

Figure 9. Selected petrographic (plane polarized light) images of samples along the Darondi Khola showing the relationship of the garnet porphyroblasts and rock textures. Garnets are outlined using bold lines. Pressure shadows and inclusion trails are indicates by lighter and dashed lines, respectively. Mineral abbreviations after Whitney and Evans (2010). Panels are labeled with sample number. The scale bar for each image is 200 μm. See Figure 4 and 5 for sample locations.

Figure 10. Compositional transects across garnets in lower LHF samples (A) DH17 and (B) DH19, and middle LHF samples (C) DH22, (D) DH23, and (E) DH75B. Distance is in analytical points, and the spacing between the points is ~20 μm. The larger black squares are the raw electron microprobe data, whereas the smaller black squares near the EPMA data points are the smoothed data used for input into the model to generate the high-resolution P-T paths. The high-resolution P-T paths predict garnet zoning, which is shown by the bold gray lines. TheriaG was used to predict the garnet zoning for the Gibb's P-T paths, and these are also indicated.

Figure 11. Compositional transects across garnets in GHC samples DH66 (two transects) in (A) spessartine, (C) grossular, (E) pyrope, and (G) almandine. Panels (B), (D), (F), and (H) are compositional transects in spessartine, grossular, pyrope, and almandine, respectively, across a garnet in sample DH61. Distance from the garnet core is in analytical points, and the spacing between the points is ~20 μm.

Figure 12. Isochemical phase diagrams from lower LHF samples DH17 (A) garnet core and (B) garnet rim, DH19 (C) core and D (rim), and mid-LHF sample DH22 (E) core and (F) rim. See Figures 4 and 5 for sample locations. Garnet-in reaction line (+Grt) and garnet growth contours (volume 0.5% increments) are overlaid on each diagram. Each core diagram was created using the rock bulk compositions reported in Table 3 and the software program Theriak-Domino. Some mineral stability fields are labeled using abbreviations after de Capitani and Petrakakis (2010) and include quartz and H_2O. For the core diagrams, isopleths of ±0.01-0.02 mole fraction spessartine (XMn), grossular (XCa), pyrope (XMg), almandine (XFe), and ±0.01-0.02 Mg-number (Mg/Fe+Mg, Mg#) of the compositional data point selected from the garnet's highest Mn content are overlain (Kohn et al., 2001). They intersect as indicated by the polygon and labeled as "T-D core." High-resolution P-T paths (DH17, n=2; DH19, n=2; DH22, n=1) were generated from garnet core-to-rim transects after the approach of Moynihan & Pattison (2013).

1065 These are compared to the P-T paths obtained using the Gibb's method for the samples using the
1066 same data by Kohn et al. (2001). The starting point of the Gibb's P-T paths is labeled with
1067 "Gibb's core." Isochemical phase diagrams for the garnet rim were created using the final
1068 effective bulk composition generated by Theriak-Domino. In this case, isopleths for the garnet
1069 compositions reported for garnet rims are overlain on the diagram, as well as matrix mineral
1070 compositions isopleths for An-content for plagioclase, Mg-number for biotite and chlorite,
1071 (Mg/Fe+Mg, Mg#-bt and Mg#-chl) (Kohn et al. 2001), when available. They intersect as
1072 indicated by the polygon and labeled as "T-D rim." These are compared to the rim P-T
1073 conditions (GB-GBMP conditions) for the samples using the same data and conventional
1074 thermobarometric approaches by Kohn et al. (2001).

1075 **Figure 13.** Isochemical phase diagrams from middle LHF samples DH23 (A) garnet core and
1076 (B) rim and DH26 (C) core and (D) rim. See Figures 4 and 5 for sample locations. Detailed
1077 caption is the same as in Figure 12. High-resolution P-T paths for sample DH23 were generated
1078 from two garnet core-to-rim transects after the approach of Moynihan & Pattison (2013). These
1079 are compared to the P-T paths obtained using the Gibb's method for the samples using the same
1080 data by Kohn et al. (2001). No data was available for the garnet transect for sample DH26, so a
1081 high-resolution P-T path was not created. In this case, the rock bulk composition (Table 3) was
1082 used for both core and rim panels.

1083 **Figure 14.** Isochemical phase diagrams from middle LHF samples DH75A (A) garnet core and
1084 (B) rim and DH75B (C) core and (D) rim. See Figures 4 and 5 for sample locations. Detailed
1085 caption is the same as in Figure 12. High-resolution P-T paths for sample DH75B were generated
1086 from garnet core-to-rim transects after the approach of Moynihan & Pattison (2013). These are
1087 compared to the P-T paths obtained using the Gibb's method for the samples using the same data
1088 by Kohn et al. (2001). The Gibb's path was also reported for sample DH75A. The starting point
1089 of the Gibb's P-T paths is labeled with "Gibb's core." The isochemical phase diagram for the
1090 garnet rim in sample DH75B was created using the final effective bulk composition generated by
1091 Theriak-Domino. In this case, isopleths for the garnet compositions reported for garnet rims are
1092 overlain on the diagram, as well as matrix mineral compositions isopleths for ±0.01 An-content
1093 for plagioclase (Kohn et al. 2001). Intersecting isopleths are indicated by the polygon and labeled
1094 as "T-D rim." No data was available for the garnet transect for sample DH75A, so a high-
1095 resolution P-T path was not created, and the rock bulk composition (Table 3) was used for both
1096 core and rim panels. In the rim panels, data are compared to the conventional P-T conditions for
1097 the samples (grey polygon) using the same data reported by Kohn et al. (2001).

1098 **Figure 15.** Isochemical phase diagrams from upper LHF samples DH58 (A) garnet core and (B)
1099 rim and (E) DH51 showing the mineral reactions only. The figure also includes isochemical
1100 phase diagrams from GHC sample DH61 (C) core and (D) rim, and DH60 (F) garnet rim data
1101 only. See Figures 4 and 5 for sample locations. Garnet-in reaction line (+Grt) and garnet growth
1102 contours (volume 0.5% increments) are overlaid on each diagram. Each diagram was created
1103 using the rock bulk compositions reported in Table 3 and the software program Theriak-Domino.
1104 Detailed caption is the same as in Figure 12. All labeled stability fields include quartz and H2O,
1105 except in panel (B), where the quartz-out reaction line is noted. The isopleths did not intersect in
1106 panels (B) and (F) but did in panel (D), as indicated by the polygon labeled as "T-D rim." In the
1107 rim panels, data are compared to the rim P-T conditions for the samples (labeled polygon) using
1108 the same data and conventional thermobarometric approaches by Kohn et al. (2001). No mineral
1109 data is available for sample DH51, so the isochemical phase diagram in panel (E) shows only

1110 reaction lines with staurolite, sillimanite, garnet, and kyanite reaction lines in bold. This sample
1111 has co-existing kyanite and staurolite, so the shaded area indicates the field where both of these
1112 minerals are stable.

1113 **Figure 16.** Isochemical phase diagrams from GHC samples (A) DH63, (B) DH66, and (C)
1114 DH67. See Figures 4 and 5 for sample locations. Garnet-in reaction line (+Grt) and garnet
1115 growth contours (volume 0.5% increments) are overlaid on each diagram. Each diagram was
1116 created using the rock bulk compositions reported in Table 3 and the software program Theriak-
1117 Domino. Some mineral stability fields are labeled using abbreviations after de Capitani and
1118 Petrakakis (2010). All labeled stability fields include quartz and H2O. For each diagram,
1119 isopleths of ±0.01-0.02 mole fraction spessartine (XMn), grossular (XCa), pyrope (XMg),
1120 almandine (XFe), and ±0.01-0.02 Mg-number (Mg/Fe+Mg, Mg#) of the compositional data
1121 point selected from the garnet's rim are overlain (Kohn et al., 2001). Isopleths of An-content for
1122 matrix plagioclase (A) and Mg# for matrix chlorite are also overlaid on the diagrams in panels
1123 (A) and (C), respectively. Mineral isopleths intersect in panels (A) and (B) as indicated by the
1124 polygon and labeled as "T-D rim." These isopleths did not intersect in panel (C). In each panel,
1125 data are compared to the rim P-T conditions for the samples (grey polygon) using the same data
1126 and conventional thermobarometric approaches by Kohn et al. (2001).

1127 **Figure 17.** Summary of the P-T conditions and paths reported in Figures 12-16. In panels (A),
1128 (C), and (E), Gibb's P-T paths are shown as bold arrows and high-resolution P-T paths are
1129 labeled with core and rim points. In panels (B), (D), and (F), rim data generated using isopleth
1130 (white polygons) and conventional thermobarometry (grey polygons) are compared. Uncertainty
1131 scales in T (±25°C) and P (±1 kbar) are shown as insets in each panel.

1132 **Figure 18.** (A) Thermal-kinematic model cross-section after Catlos et al. (2018) showing the
1133 MCT (dark line) and MBT (white line) from 25 to 8 Ma. The MCT and MBT sole into the MHT
1134 at depth. Isothermal sections in degree increments are indicated by the scale bar. The isotherms
1135 show the thermal situation at 18 Ma after MCT slip. Example sample trajectories on the diagram
1136 are represented by arrows with dots at the initial and heads at the final position. The MCT is
1137 active from 25 to 18 Ma, whereas slip transfers to the MBT from 15 to 8 Ma. (B) The model
1138 cross-section of the reactivation of the MCT shear zone from 8 to 2 Ma. Both the MCT and
1139 MCT-I sole into the MHT at depth. This panel represents the thermal situation at 6 Ma right
1140 before the development of MCT shear zone inverted metamorphism. Example sample
1141 trajectories are shown. (C) P-T diagram showing the trajectories of the model predictions for
1142 samples panels A and B and high-resolution P-T paths for the Darondi Khola samples. Sample
1143 DH75B is identified. Panels (D) and (E) show the same model predictions but high-resolution P-
1144 T paths from the Marsyangdi River (Catlos et al., 2018) and Bhagirathi River transects (Catlos et
1145 al., 2020).

2413   [a] See Figure 3 for sample locations.

Figure 1. Geological map of the Himalayas after Yin (2006). Geological map of the Himalayas after Yin (2006). See Figure 2 for a cross-section through central Nepal and Figures 3-5 for the sample transect taken across the MCT shear zone along the Darondi Khola. See supplementary files for this figure in color.

Figure 2. Generalized cross-section through the Himalayas in central Nepal after DeCelles (2015) and Robinson et al. (2006). See additional cross-sections in the range in DeCelles et al. (2020).

Figure 3. Generalized geological map of the Annapurna-Manaslu-Ganesh region of central Nepal after Colchen et al. (1980). Isograds are dashed and labeled: bt= biotite, grt= garnet; ky= kyanite; sta= staurolite; sil= sillimanite; pyx= pyroxene, carbonate lithologies. STDS? = the presence of the South Tibetan Detachment is debated; MCT= Main Central Thrust; MCT-I?= the presence of Arita's (1983) thrust at the base of the MCT shear zone is debated.

Figure 4. Sample location map from rocks collected along the Darondi Khola. The contour interval is 500 ft. See Figure 3 for the location of this transect on the geological map of the Himalayas. Samples are indicated by "DH#" in the text. Isograds are dashed and labeled (grt= garnet; stau= staurolite). See figure 5 for a cross-section along A-A'.

Figure 5. Cross-section across the Darondi Khola section showing available muscovite $^{40}Ar/^{39}Ar$ and Th-Pb ages after Catlos et al. (2001). See Figure 4 for line of section.

Figure 6. Cross-sections of early models of Himalayan inverted metamorphism and leucogranite formation. (A) The "hot-iron" model of LeFort 1975. (B) Juxtaposing right-way-up metamorphic isograds after Hubbard (1996). (C) A combination of models in panels (A) and (B) after Searle and Rex (1989). Wedge extrusion models after (D) Hodges et al. (1993) and (E) Harris & Massey (1994).

Figure 7. Cross-sections of early kinematic models of Himalayan inverted metamorphism and leucogranite formation. (A) After Molnar and England (1990). (B) After Huerta et al. (1998). (C) After Harrison et al. (1989). (D) After Nelson et al. (1996).

Figure 8. (A) An illustration of the critical taper model. (B) Schematic of channel flow and wedge extrusion. (C) A combination of critical taper and tectonic wedging of the GHC. A "*" indicates an incipient fault. (D) Illustration of GHC tectonic wedging after Webb et al. (2011). Panels (E) and (F) show the final geometry of the range, which has affected the position and definition of the MCT. Panel (G) showing the development of the MCT shear zone as rocks shown as squares within the footwall accrete to the hanging wall of the MCT. Faults within the GHC include the Kalopani shear zone (KSZ) and High Himalayan discontinuity (HHD). Panels (A), (B), (C), and (E) are after Cottle et al. (2015), panel (F) is after Searle et al. (2008), and panel (G) after Carosi et al. (2006).
Figure 9. Selected petrographic (plane-polarized light) images of samples along the Darondi Khola showing the relationship of the garnet porphyroblasts and rock textures. Garnets are outlined using bold lines. Pressure shadows and inclusion trails are indicated by lighter and dashed lines, respectively. Mineral abbreviations after Whitney and Evans (2010). Panels are labeled with the sample numbers. The scale bar for each image is 200 um. See Figures 4 and 5 for sample locations. See supplementary files for this figure in color.

Figure 10. Compositional transects across garnets in lower LHF samples (A) DH17 and (B) DH19, and middle LHF samples (C) DH22, (D) DH23, and (E) DH75B. Distance is in analytical points, and the spacing between the points is ~20μm. The larger black squares are the raw electron microprobe data, whereas the smaller black squares near the EPMA data points are the smoothed data used for input into the model to generate the high-resolution P-T paths. The high-resolution P-T paths predict garnet zoning, which is shown by the bold gray lines. TheriaG was used to predict the garnet zoning for the Gibb's P-T paths, and these are also indicated.

Figure 11. Compositional transects across garnets in GHC samples DH66 (two transects) in (A) spessartine, (C) grossular, (E) pyrope, and (G) almandine. Panels (B), (D), (F), and (H) are compositional transects in spessartine, grossular, pyrope, and almandine, respectively, across a garnet in sample DH61. Distance from the garnet core is in analytical points, and the spacing between the points is ~20μm.

Figure 12. Isochemical phase diagrams from lower LHF samples DH17 (A) garnet core and (B) garnet rim, DH19 (C) core and D (rim), and mid-LHF sample DH22 (E) core and (F) rim. See text for entire figure caption.
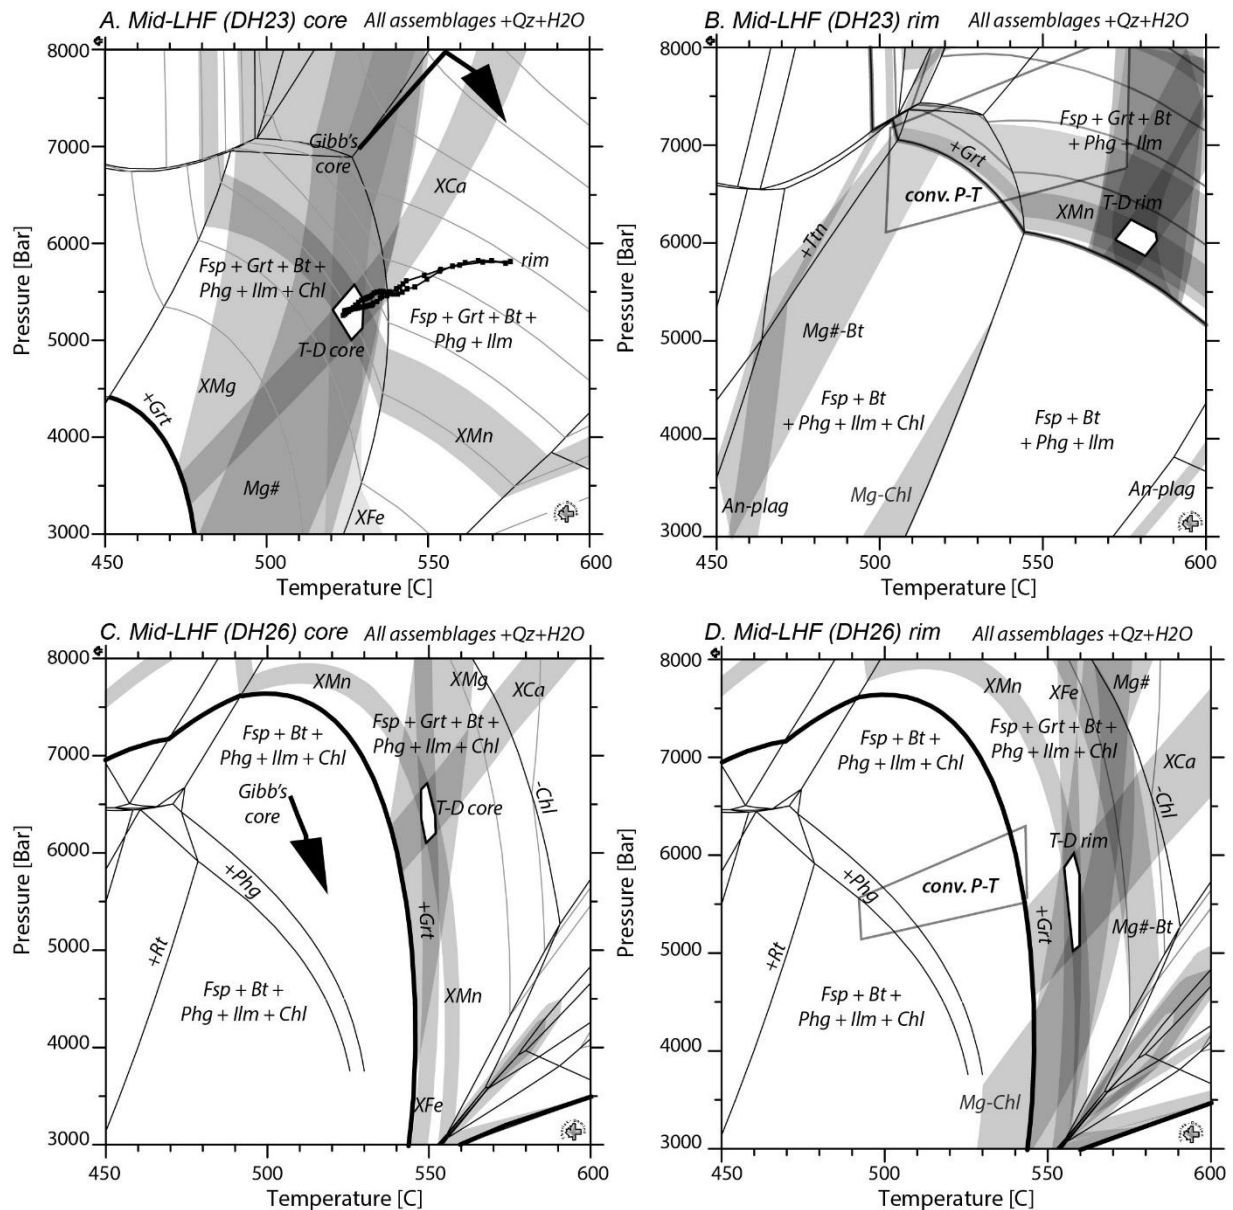

Figure 13. Isochemical phase diagrams from middle LHF samples DH23 (A) garnet core and (B) rim and DH26 (C) core and (D) rim. See Figures 4 and 5 for sample locations. Detailed caption is the same as in Figure 12. High-resolution P-T paths for sample DH23 were generated from two garnet core-to-rim transects after the approach of Moynihan & Pattison (2013). These are compared to the P-T paths obtained using the Gibb's method for the samples using the same data by Kohn et al. (2001). No data was available for the garnet transect for sample DH26, so a high-resolution P-T path was not created. In this case, the rock bulk composition (Table 3) was used for both core and rim panels.
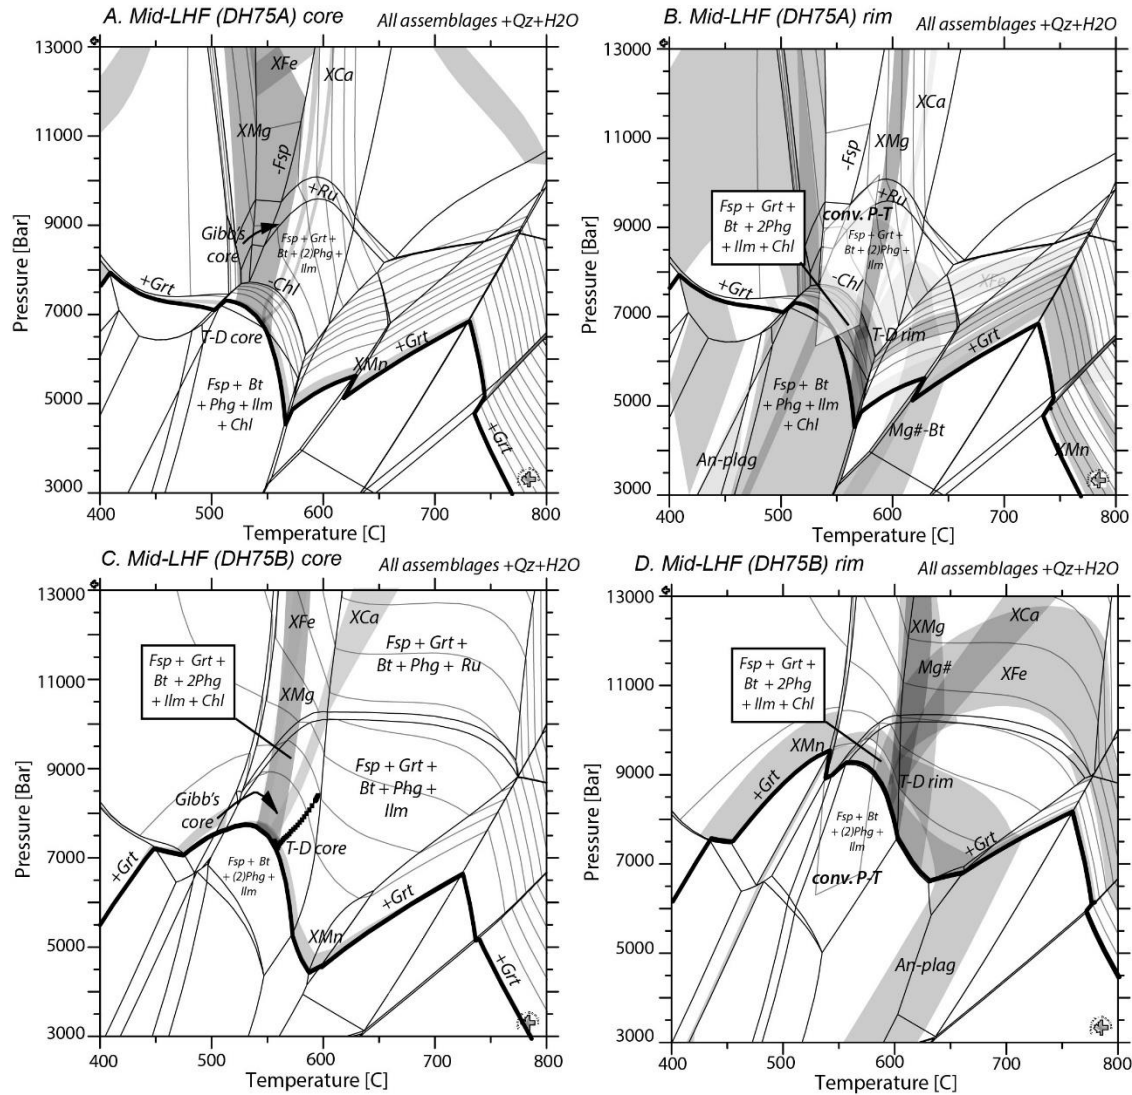

Figure 14. Isochemical phase diagrams from middle LHF samples DH75A (A) garnet core and (B) rim and DH75B (C) core and (D) rim. See Figures 4 and 5 for sample locations. Detailed caption is the same as in Figure 12. High-resolution P-T paths for sample DH75B were generated from garnet core-to-rim transects after the approach of Moynihan & Pattison (2013). These are compared to the P-T paths obtained using the Gibb's method for the samples using the same data by Kohn et al. (2001). The Gibb's path was also reported for sample DH75A. The starting point of the Gibb's P-T paths is labeled with "Gibb's core." The isochemical phase diagram for the garnet rim in sample DH75B was created using the final effective bulk composition generated by Theriak-Domino. In this case, isopleths for the garnet compositions reported for garnet rims are overlain on the diagram, as well as matrix mineral compositions isopleths for ±0.01 An-content for plagioclase (Kohn et al. 2001). Intersecting isopleths are indicated by the polygon and labeled as "T-D rim." No data was available for the garnet transect for sample DH75A, so a high-resolution P-T path was not created, and the rock bulk composition (Table 3) was used for both core and rim panels. In the rim panels, data are compared to the conventional P-T conditions for the samples (grey polygon) using the same data reported by Kohn et al. (2001).
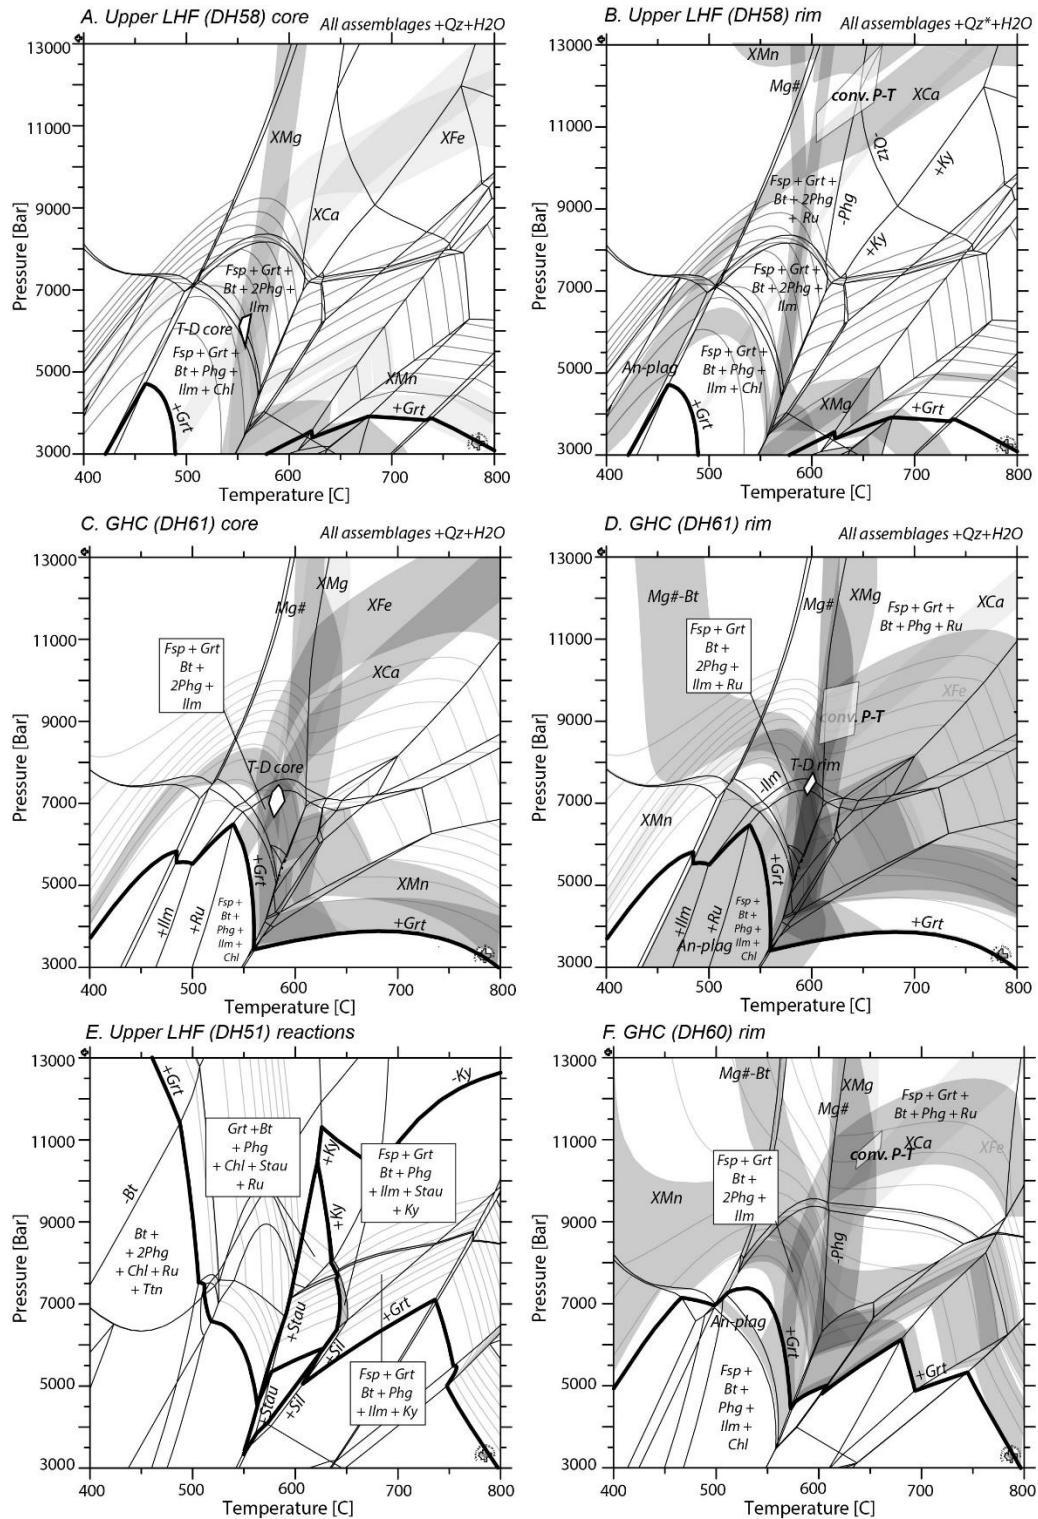

Figure 15. Isochemical phase diagrams from upper LHF samples DH58 (A) garnet core and (B) rim and (E) DH51 showing the mineral reactions only. The figure also includes isochemical phase diagrams from GHC sample DH61 (C) core and (D) rim, and DH60 (F) garnet rim data only. See text for detailed caption.
Figure 16. Isochemical phase diagrams from GHC samples (A) DH63, (B) DH66, and (C) DH67. See Figures 4 and 5 for sample locations. See manuscript text for detailed caption.
Figure 17. Summary of the P-T conditions and paths reported in Figures 12-16. In panels (A), (C), and (E), Gibb's P-T paths are shown as bold arrows and high-resolution P-T paths are labeled with core and rim points. In panels (B), (D), and (F), rim data generated using isopleth (white polygons) and conventional thermobarometry (grey polygons) are compared. Uncertainty scales in T (±25°C) and P (±1 kbar) are shown as insets in each panel.
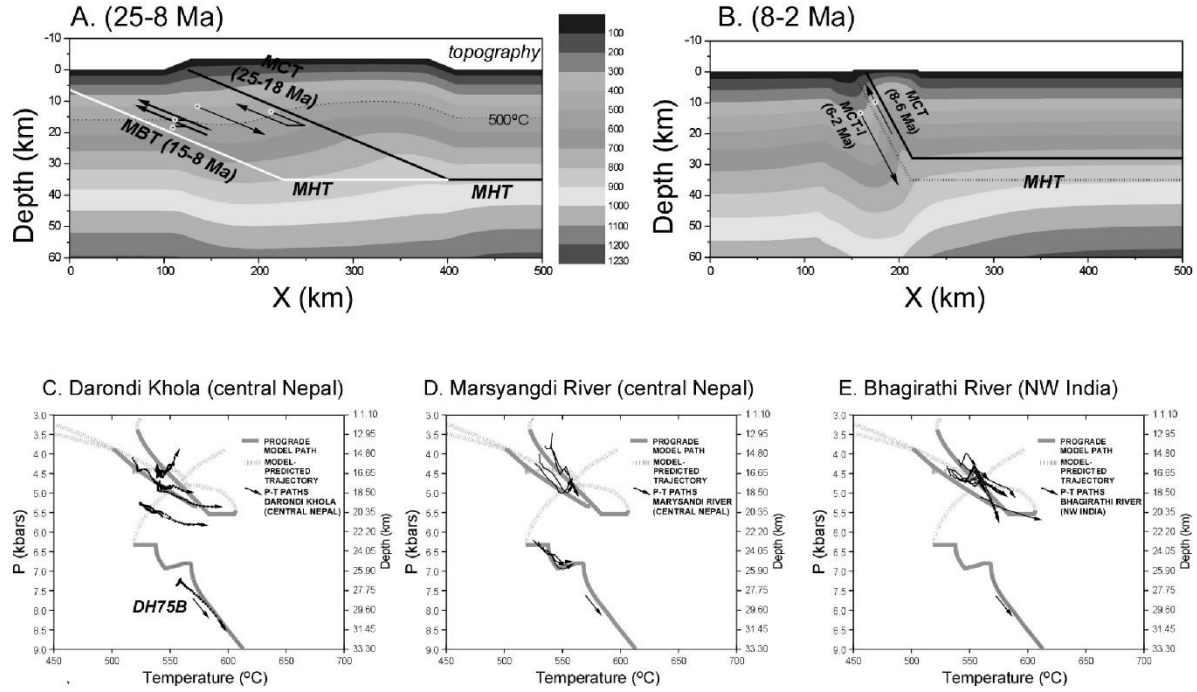

Figure 18. (A) Thermal-kinematic model cross-section after Catlos et al. (2018) showing the MCT (dark line) and MBT (white line) from 25 to 8 Ma. The MCT and MBT sole into the MHT at depth. Isothermal sections in degree increments are indicated by the scale bar. The isotherms show the thermal situation at 18 Ma after MCT slip. Example sample trajectories on the diagram are represented by arrows with dots at the initial and heads at the final position. The MCT is active from 25 to 18 Ma, whereas slip transfers to the MBT from 15 to 8 Ma. (B) The model cross-section of the reactivation of the MCT shear zone from 8 to 2 Ma. Both the MCT and MCT-I sole into the MHT at depth. This panel represents the thermal situation at 6 Ma right before the development of MCT shear zone inverted metamorphism. Example sample trajectories are shown. (C) P-T diagram showing the trajectories of the model predictions for samples panels A and B and high-resolution P-T paths for the Darondi Khola samples. Sample DH75B is identified. Panels (D) and (E) show the same model predictions but high-resolution P-T paths from the Marsyangdi River (Catlos et al., 2018) and Bhagirathi River transects (Catlos et al., 2020). See supplementary files for this figure in color.
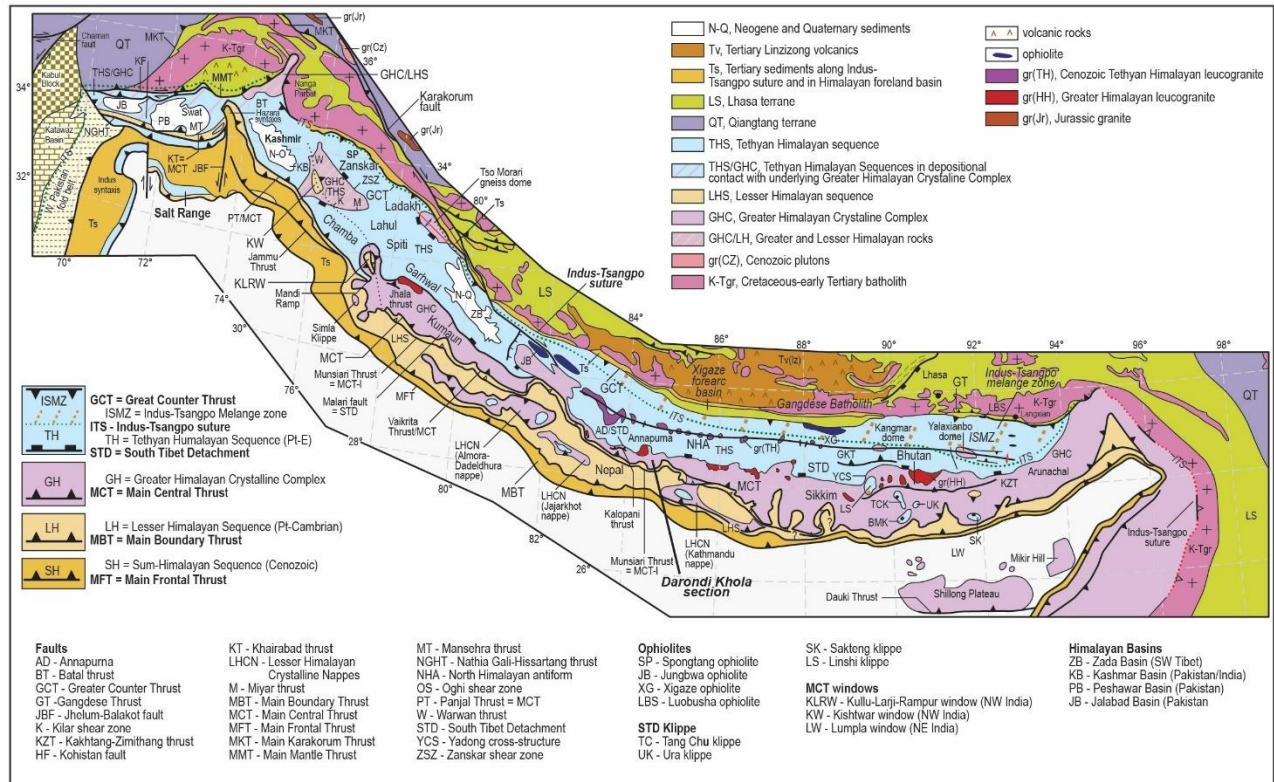

Figure S1. Geological map of the Himalayas after Yin (2006). Geological map of the Himalayas after Yin (2006). See Figure 2 for a cross-section through central Nepal and Figures 3-5 for the sample transect taken across the MCT shear zone along the Darondi Khola.
**Figure S9.** Selected petrographic (plane polarized light) images of samples along the Darondi Khola showing the relationship of the garnet porphyroblasts and rock textures. Garnets are outlined using bold lines. Pressure shadows and inclusion trails are indicates by lighter and dashed lines, respectively. Mineral abbreviations after Whitney and Evans (2010). Panels are labeled with sample number. The scale bar for each image is 200 μm. See Figures 4 and 5 for sample locations.
