Key Points:

- Theory and global simulations of magnetopause surface waves' effects on the aurorae, ionosphere, and ground magnetic field are investigated
- We predict poleward-moving periodic aurora, convection vortices, and ground pulsations, with larger latitudinal scales than Alfvén modes
- Amplitudes of all signals peak near the projection of the inner/equatorward edge of the magnetopause rather than the open–closed boundary

Corresponding author: Martin Archer, `m.archer10@imperial.ac.uk`

Abstract

Surface waves on Earth's magnetopause have a controlling effect upon global magneto-spheric dynamics. Since spacecraft provide sparse *in situ* observation points, remote sensing these modes using ground-based instruments in the polar regions is desirable. However, many open conceptual questions on the expected signatures remain. Therefore, we provide predictions of key qualitative features expected in auroral, ionospheric, and ground magnetic observations through both magnetohydrodynamic theory and a global coupled magnetosphere-ionosphere simulation of a magnetopause surface eigenmode. These show monochromatic oscillatory field-aligned currents, due to both the surface mode and its non-resonant Alfvén coupling, are present throughout the magnetosphere. The currents peak in amplitude at the equatorward edge of the magnetopause boundary layer, not the open-closed boundary as previously thought. They also exhibit slow poleward phase motion rather than being purely evanescent. We suggest the upward field-aligned current perturbations may result in periodic auroral brightenings. In the ionosphere, convection vortices circulate the poleward moving field-aligned current structures. Finally, surface mode signals are predicted in the ground magnetic field, with ionospheric Hall currents rotating perturbations by approximately (but not exactly) $90°$ compared to the magnetosphere. Thus typical dayside magnetopause surface modes should be strongest in the East-West ground magnetic field component. Overall, all ground-based signatures of the magnetopause surface mode are predicted to have the same frequency across L-shells, amplitudes that maximise near the magnetopause's equatorward edge, and larger latitudinal scales than for field line resonance. Implications in terms of ionospheric Joule heating and geomagnetically induced currents are discussed.

Plain Language Summary

Waves on the boundary of the magnetosphere, the magnetic shield established by the interplay of the solar wind with Earth's magnetic field, play a controlling role on energy flow into our space environment. While these waves can be observed as they pass over satellites in orbit, due to the small number of suitable satellites available it would be beneficial to be able to detect these waves from the surface of the Earth with instruments that measure the northern/southern lights, motion of the top of our atmosphere, or magnetic field on the ground. However, we do not currently understand what the signs of these waves should look like in such instruments. In this paper we develop theory and

use computer simulations of these boundary waves to predict key features one might expect to measure from the ground. Based on these predictions, we also discuss how the waves might contribute to the hazards of space weather.

1 Introduction

The interaction between the solar wind and Earth's magnetosphere results in a zoo of dynamical plasma waves. Those with wavelengths comparable to the size of the magnetosphere are well described by magnetohydrodynamics (MHD) and due to their corresponding frequencies, ~ 0.1–$100\,\mathrm{mHz}$ (Jacobs et al., 1964), are known as ultra-low frequency (ULF) waves. ULF waves play important roles in space weather processes such as substorms (e.g. Kepko & Kivelson, 1999), wave-wave (e.g. Li et al., 2011) and wave-particle (e.g. Turner et al., 2012) interactions, magnetosphere-ionosphere (MI) coupling (e.g. Keling, 2009), and geomagnetically induced currents (e.g. Heyns et al., 2021). In addition to familiar Alfvén and fast/slow magnetosonic body MHD waves (those which may freely propagate through plasma volumes), sharp discontinuities separating regions with different physical parameters, such as the magnetopause and plasmapause, allow for collective modes – surface waves (Kruskal & Schwartzschild, 1954; Goedbloed, 1971; Chen & Hasegawa, 1974). Surface modes lead to mass, momentum, and energy transport across the boundary, consequently manifesting a controlling effect on global magnetospheric wave dynamics (e.g. Kivelson & Chen, 1995). As with the body waves, theory behind surface waves has largely been developed in simplified box model magnetospheres, typically with homogeneous half-spaces. Within these the surface mode is inherently compressional, being described by two evanescent fast magnetosonic waves (one in each half-space such that perturbations decay with distance from the boundary) that are joined by boundary conditions that ensure pressure balance and continuity of normal displacement across the interface (Pu & Kivelson, 1983; Plaschke & Glassmeier, 2011). On each side the magnetosonic relation

$$k_n^2 = -k_\perp^2 - k_\parallel^2 + \frac{\omega^4}{\omega^2 v_A^2 + c_s^2 \left(\omega^2 - k_\parallel^2 v_A^2 \right)} \tag{1}$$

thus holds, where n represents the direction normal to the discontinuity, and v_A and c_s are the Alfvén and sound speeds respectively (see Notation). Under incompressibility, the last term of equation 1 may be neglected and the normal wavenumber is imaginary.

88 In contrast, if this assumption is not valid or if waves are damped/unstable then k_n may

89 be complex, exhibiting both evanescence and normal phase motion (Pu & Kivelson, 1983;

90 Archer et al., 2021, hereafter A21). The dispersion relation for incompressible surface

91 waves in a box model can be analytically solved. Applied to the magnetopause, for zero

92 magnetic shear across boundary (equivalent to northward interplanetary magnetic field;

93 IMF) and no background flows, it is (Plaschke & Glassmeier, 2011)

$$\omega = k_\parallel \sqrt{\frac{B_{msp}^2 + B_{msh}^2}{\mu_0 \left(\rho_{msp} + \rho_{msh}\right)}} \approx k_\parallel \frac{B_{msp}}{\sqrt{\mu_0 \rho_{msh}}} \tag{2}$$

94 where msp refers to the magnetosphere and msh the magnetosheath. The boundary con-

95 ditions of closed magnetic field lines at the northern and southern ionospheres impose

96 quantised wavelengths along the field (Chen & Hasegawa, 1974), forming an eigenmode

97 of the system. On the dayside, where magnetosheath flows are smaller, this magnetopause

98 surface eigenmode (MSE) is expected to occupy frequencies below $2 \, \text{mHz}$ (Plaschke et

99 al., 2009; Archer & Plaschke, 2015). Such low eigenfrequencies are a result of the com-

100 bination of magnetic fields and densities from both sides of the magnetopause, making

101 it the lowest frequency magnetospheric normal mode and highly penetrating. However,

102 in the flanks the faster magnetosheath velocities are expected to dictate the wave fre-

103 quency (Plaschke & Glassmeier, 2011; O. Kozyreva et al., 2019), rather than the extent

104 of the field lines, yielding shorter wavelengths and periods. Chen & Hasegawa (1974) ar-

105 gue that surface modes on a boundary of finite thickness might be strongly damped, with

106 this being primarily due to mode conversion to Alfvén waves and spatial phase mixing

107 within the boundary layer, rather than dissipation in the ionosphere or due to the pres-

108 ence of the ionosphere-Earth boundary.

109 Magnetopause surface modes may be excited by several driving processes, either

110 external or internal to the magnetosphere. External mechanisms include upstream (so-

111 lar wind, foreshock, or magnetosheath) pressure variations, which may be either quasi-

112 periodic (e.g. Sibeck et al., 1989) or impulsive (e.g. Shue et al., 2009), and the Kelvin-

113 Helmholtz instability (KHI) due to velocity shears (e.g. Fairfield et al., 2000). Internal

114 processes, such as the drift mirror instability, can generate compressional ULF waves within

115 the low- and high-latitude magnetospheric boundary layer (Constantinescu et al., 2009;

116 Nykyri et al., 2021), which may also lead to surface wave growth at the magnetopause.

117 There has been much evidence of magnetopause surface waves from spacecraft observa-

118 tions, particularly in the magnetospheric flanks where KHI-generated waves are thought

119 to be prevalent (e.g. Southwood, 1968; Kavosi & Raeder, 2015). However, only recently

120 was MSE, as proposed by Chen & Hasegawa (1974), discovered through multi-spacecraft

121 observations on the dayside magnetosphere following impulsive external driving (Archer

122 et al., 2019).

123   Understanding the fundamental properties and potential impacts of magnetopause

124 surface modes within a realistic magnetospheric environment has necessitated the use

125 of global MHD simulations (e.g. Claudepierre et al., 2008; Hartinger et al., 2015, hence-

126 forth H15). These have revealed surface waves might lead the entire magnetosphere to

127 oscillate at the surface mode frequency by coupling to body MHD waves such as Alfvénic

128 field line resonance (FLR) or fast magnetosonic waveguide modes (Merkin et al., 2013;

129 A21). Confirming such a global system response is challenging with *in situ* spacecraft

130 observations. For any particular event, only a few observation points are available from

131 current missions (e.g. Cluster, THEMIS, MMS). Statistical studies are also challenging

132 due to the highly variable conditions present throughout geospace, which influence the

133 properties of ULF waves (Archer & Plaschke, 2015; Archer et al., 2015). On the other

134 hand, ground-based instruments such as all-sky imagers (e.g. Donovan et al., 2006; Rae

135 et al., 2012), radar (e.g. Walker et al., 1979; Nishitani et al., 2019), and ground magne-

136 tometers (e.g. Mathie et al., 1999; Gjerloev, 2009) provide good coverage of the near-

137 Earth signatures of ULF waves. While they offer the possibility of remote sensing the

138 magnetopause surface mode, at present this is challenging as we need to understand how

139 its energy couples through the intervening regions. The theory behind ionospheric and

140 ground effects of ULF waves has focused on the Alfvén mode (e.g. Hughes & Southwood,

141 1974, 1976), whereas the surface mode is fundamentally compressional. Several open con-

142 ceptual questions about the nature of surface modes in these regions remain. It is also

143 difficult to confidently distinguish with ground-based instruments between surface waves,

144 either on the magnetopause (Kivelson & Southwood, 1991; Glassmeier, 1992; Glassmeier

145 & Heppner, 1992) or low latitude boundary layer (Sibeck, 1990; Lyatsky & Sibeck, 1997),

146 and propagating body waves near these boundaries (Tamao, 1964a,b; Araki & Nagano,

147 1988; Slinker et al., 1999), especially as surface waves may excite secondary body waves

148 (Southwood, 1974; A21).

149   It is not clear whether magnetopause surface waves are expected to directly affect

150 the ionosphere. Kivelson & Southwood (1988) consider the currents and boundary con-

151 ditions associated with MHD waves in a box model. They argue surface waves affect the

ionosphere only across the thin transition layer. This work was, however, applied to the plasmapause, avoiding the complication with the magnetopause that adjacent magnetosheath field lines do not terminate in the polar cap (O. Kozyreva et al., 2019). Other theoretical models have focused on closed field lines Earthward of the boundary, considering field-aligned current (FAC) generation due to coupling between the compressional and Alfvén modes in an inhomogeneous/curvilinear magnetosphere (Sibeck, 1990; Southwood & Kivelson, 1990, 1991). The models all predict FACs communicate (tailward travelling) magnetopause disturbances to the ionosphere, resulting in so-called travelling convection vortices (TCVs). These were first inferred from ground magnetometer observations (Friis-Christensen et al., 1988) and can also be observed directly through radar observations (e.g. Bristow et al., 1995). Discrete auroral emission might also result from precipitating electrons which carry these FACs (Greenwald & Walker, 1980). The models, however, do not make predictions about the magnetopause surface mode directly. In particular, they circumvent the question of how the ionosphere is affected by field lines within (and close to) the boundary layer. Furthermore, auroral brightenings and TCVs are expected for any magnetospheric process which results in FACs, e.g. field line resonance (Greenwald & Walker, 1980), hence predictions of how to distinguish effects caused by surface waves and other mechanisms are required.

The direct ground magnetic field signatures of surface waves are also poorly understood, even during confirmed case studies from *in situ* spacecraft observations (Archer et al., 2019; He et al., 2020). Kivelson & Southwood (1988) suggest the surface mode may be screened from the ground due to the thin ionospheric region affected, similar to with small wavelength Alfvén modes (Hughes & Southwood, 1976). They conclude the magnetic signal on the ground might be similar to that in the magnetosphere, i.e. not rotated by $\sim 90°$ as Alfvén waves are (Hughes, 1974; Hughes & Southwood, 1974). However, vortical ground magnetic signals are often observed by high-latitude magnetometer networks, being associated with TCVs (e.g. Glassmeier, 1992; Glassmeier & Heppner, 1992; Hwang et al., 2022). This potentially calls the theoretical prediction into question or signals intermediate Alfvén waves may be involved.

Finally, it is not clear where auroral, ionospheric, and ground magnetic signals of magnetopause surface waves should map to. Intuitively one might expect them around the open-closed boundary (OCB) of magnetic field lines. O. Kozyreva et al. (2019) suggest that short-lived quasi-periodic motions of the OCB in auroral keograms and ground

185 magnetic oscillations near the OCB with large latitudinal scales and similar periodic-

186 ities across L-shells might distinguish magnetopause surface modes from the Alfvén con-

187 tinuum, presenting potential case studies. However, Pc5-6 band (periods ~ 3–$15\,\mathrm{min}$)

188 oscillations in ground magnetometer data have been shown to peak systematically equa-

189 torward of optical and ionospheric proxies for the cusp OCB by 1–3° (V. A. Pilipenko

190 et al., 2017, 2018; O. Kozyreva et al., 2019). In the absence of conjugate space-based ob-

191 servations, conclusions have been mixed over whether these results relate to MSE and

192 what the implications are for its excitation efficiency.

193 To resolve these open questions, we employ MHD theory and a global MI-coupling

194 simulation of MSE. Since MSE are the lowest frequency normal mode of the magneto-

195 sphere, they allow us to better understand the direct effects of surface waves on the day-

196 side aurorae, ionosphere, and ground magnetic field without the complications of sec-

197 ondary coupled wave modes. We aim to detail the physical processes that lead to these

198 signatures, yielding specific qualitative predictions that might enable crucial remote-sensing

199 observations of magnetopause surface modes in the future.

2 Box Model Theory

201 To gain initial insight, we first consider a box model magnetosphere. These straighten

202 the geomagnetic field lines into a uniform field bounded by northern and southern iono-

203 spheres (Radoski, 1971; Southwood, 1974).

2.1 Method

205 We use the same model setup as Plaschke & Glassmeier (2011), who derived the

206 magnetospheric signatures of incompressible MSE. The model equilibrium consists of two

207 uniform half-spaces, the magnetosheath and magnetosphere, separated by the magne-

208 topause discontinuity at $x = 0$. The geomagnetic field is confined to $x > 0$ and points

209 in the z-direction. Thus close to the MI-interface, x is directed equatorward and y is west-

210 ward. Plaschke & Glassmeier (2011) showed the currents associated with surface waves

211 in a box model are sinusoidal and contained within the infinitesimally thin boundary,

212 which we refer to as magnetopause currents. These magnetopause currents have field-

213 aligned components, in particular at the MI-interface. Fast magnetosonic waves are not

214 expected to have FACs in infinite uniform media, only Alfvén waves lead to these, hence

215 generally fast magnetosonic modes are not expected to couple to the ionosphere. The

216 surface mode, however, is unique as a fast mode which supports FACs at the interface

217 of the two uniform half-spaces due to the nonuniformity at this location. A complemen-

218 tary view considers amplitudes of the different MHD modes through the divergence and

219 curl of electric field perturbations $\delta\mathbf{E}$ (Yoshikawa & Itonaga, 1996, 2000), where $(\nabla \times \delta\mathbf{E})_{\parallel}$

220 gives the fast/compressional mode and $\nabla\cdot\delta\mathbf{E}$ yields the Alfvén/shear mode. Applying

221 this to the Plaschke & Glassmeier (2011) analytic solutions reveals that in the two uni-

222 form half-spaces the surface wave is purely compressional ($\nabla\cdot\delta\mathbf{E} = 0$), whereas inside

223 the boundary layer there are non-zero amplitudes for both shear and compressional modes

224 (via Gauss' and Stokes' theorems respectively).

225 Plaschke & Glassmeier (2011) suggested the surface waves' FACs at the MI-interface

226 might close in the ionosphere. We, therefore, extend their model to incorporate a finite

227 conductivity thin-shell ionosphere using the electrostatic MI-coupling method (Wolf, 1975;

228 Goodman, 1995; Janhunen, 1998; Ridley et al., 2004), valid since surface waves occupy

229 such low frequencies (Lotko, 2004). This works by determining the disturbance ionospheric

230 potential $\delta\psi_{isp}$ through current continuity, which for the northern hemisphere is given

231 by

$$
\begin{aligned}
\delta j_r \;&= \nabla_{\perp} \cdot \left(\mathbf{\Sigma} \cdot \nabla \delta\psi_{isp}\right)_{\perp} \\
&= \nabla_{\perp} \cdot \left[\begin{pmatrix} \Sigma_P & -\Sigma_H \\ \Sigma_H & \Sigma_P \end{pmatrix} \cdot \nabla \delta\psi_{isp} \right] \\
&= \Sigma_P \left(\frac{\partial^2}{\partial x^2} + \frac{\partial^2}{\partial y^2} \right) \delta\psi_{isp}
\end{aligned}
\tag{3}
$$

232 where δj_r are the vertical currents (pointing radially/upwards) at the MI-interface from

233 Plaschke & Glassmeier (2011), and $\mathbf{\Sigma}$ denotes the height-integrated conductivity ten-

234 sor consisting of Pedersen (P) and Hall (H) conductances, both assumed to be uniform.

235 Equation 3 is solved numerically using the 2D Laplacian's Green's function

$$
\delta\psi_{isp}\left(x,y\right) = \iint dx' dy' \frac{\delta j_r\left(x', y'\right)}{\Sigma_P} \frac{\ln\left(\sqrt{(x-x')^2 + (y-y')^2}\right)}{2\pi}
\tag{4}
$$

236 from which the ionospheric electric field and currents are determined. Finally, magnetic

237 field perturbations at some location $\mathbf{r}$ are calculated using the Biot-Savart law

$$
\delta\mathbf{B}\left(\mathbf{r}\right) = \frac{\mu_0}{4\pi} \iiint d^3\mathbf{r}' \frac{\delta\mathbf{j}\left(\mathbf{r}'\right) \times \left(\mathbf{r} - \mathbf{r}'\right)}{\left|\left(\mathbf{r} - \mathbf{r}'\right)\right|^3}
\tag{5}
$$

238 which can be computed for the magnetopause, Pedersen, and Hall current systems sep-

239 arately (Rastätter et al., 2014).

2.2 Results

241 The model used typical dayside field line lengths of $25\,\mathrm{R_E}$, ionospheric conductances

242 $\Sigma_P = \Sigma_H = 5\,\mathrm{S}$ valid for sunlit high-latitude regions, and zero magnetic shear across

243 the magnetopause. We present results for one example surface mode, a localised pertur-

244 bation with wavelength of $2\pi/k_z = 50\,\mathrm{R_E}$ along the field (fundamental mode) and $2\pi/k_y =$

245 $10\,\mathrm{R_E}$ azimuthally, based on previous simulation results (A21; Archer et al., 2022, here-

246 after A22). This is applied to a single time, shown in Figure 1a, since the entire pattern

247 will propagate along y. The model size is twice the dimensions of that shown, to mit-

248 igate potential edge effects.

249 Figure 1a shows the Pedersen currents (purple) provide current closure in the East-

250 West direction for the FACs. This is unlike in FLRs where closure is typically North-

251 South (e.g. Greenwald & Walker, 1980). While the Pedersen currents are strongest along

252 the OCB, due to the finite conductivity they spread out significantly across the ionosphere

253 too. Their magnitudes fall off with distance from the OCB, but extend well beyond the

254 $1.56\,\mathrm{R_E}$ evanescent e-folding scale of the magnetospheric signatures, given by $|k_x|^{-1} =$

255 $\left(k_y^2 + k_z^2\right)^{-1/2}$. Pedersen current patterns result in Hall current vortices (green) surround-

256 ing the FAC sources/sinks at the OCB. Their sense of rotation is clockwise for down-

257 ward FACs and anticlockwise for upward FACs. Hall current magnitudes decrease with

258 distance identically to the Pedersen currents, due to the conductivities used. Since iono-

259 spheric velocities are given by the $\mathbf{E} \times \mathbf{B}$ drift, Pedersen currents result in TCVs colo-

260 cated with the Hall current vortices but with the opposite sense of rotation. As the back-

261 ground magnetic field is uniform in this model, convection speeds also fall off similarly

262 with distance from the OCB.

263 We now focus on the directions of the horizontal magnetic field perturbations, shown

264 in Figure 1a as black arrows above and below the ionosphere. The ground magnetic sig-

265 nals exhibit a vortical pattern centred at the midpoint of the FACs. Figure 1b shows the

266 relative contributions of different current systems (colours) to the overall horizontal field

267 (black). This reveals the field points mainly in the direction of the Hall current contri-

268 bution, with magnetopause and Pedersen current magnetic fields largely opposing one

269   another. In the case of an infinite plane Alfvén wave (for vertical background field and

270   uniform conductances) the ground magnetic field is entirely dictated by Hall currents

271   with FAC and Pedersen contributions cancelling (Hughes, 1974). However, we notice in

272   Figure 1b that the total horizontal field is slightly misaligned from the Hall current con-

273   tribution, due to magnetopause and Pedersen contributions no longer perfectly cancelling.

274   This occurs because, in the case of a surface wave, while the largest contributions to the

275   ground field from the Hall and Pedersen currents still arise from above the ground sta-

276   tion, the FACs into the ionosphere are confined to the OCB and thus are generally not

277   directly overhead. This results in the misalignment growing with distance from the OCB,

278   as well as very close to the OCB but on the outer edges of the localised FACs, as can

279   be seen in Figure 1b.

280   Figure 1a shows that the horizontal field perturbations above and below the iono-

281   sphere are rotated from one another, seemingly by right angles. While an exactly 90°

282   rotation would be expected for a plane Alfvén wave here (Hughes & Southwood, 1974;

283   Hughes, 1974), Kivelson & Southwood (1988) suggested that no rotation in the field might

284   occur sufficiently far from a surface wave. We find this not to be the case for up to the

285   ~ 6 e-folding lengths shown. Panel c compares the directions of the ground field (black)

286   to those at two altitudes above the ionosphere (greys). From these it is clear this rota-

287   tion is not 90° and that the rotation angle also depends on altitude. This is because iono-

288   spheric Pedersen and Hall currents contribute to the magnetic field above the ionosphere,

289   as evidenced by the blue lines which show only the field due to magnetopause currents

290   (less sensitive to altitude). The difference between the grey and blue arrows grow with

291   distance from the OCB, for similar reasons as to which current systems are closest. Such

292   an effect would be less prominent with a plane Alfvén wave since FACs permeate space

293   above the ionosphere. Above the ionosphere, the direction of the magnetic field due to

294   only magnetopause currents are much closer to 90° different from the ground than the

295   total field. The discrepancy from a right angle is exactly that due to the non-cancellation

296   of magnetopause and Pedersen currents on the ground shown in panel b. This discrep-

297   ancy will vary quantitatively with ionospheric conductivity and surface mode wavelength.

298   We now consider both horizontal and vertical components of the ground magnetic

299   field. The horizontal field magnitudes shown in Figure 1d clearly show an overall decreas-

300   ing trend with distance from the OCB (colours). The vertical component has the same

301   sense as the FACs into the ionosphere, i.e. reversing direction at $y = 0$. The vertical

302   component's magnitude also decreases with distance from the OCB. Close to the OCB

303   the vertical component has root mean squared (RMS) values up to ~ 3 times larger than

304   the horizontal component. However, its RMS drops off much more quickly with distance,

305   with them becoming equal at $x \sim 0.45\,\mathrm{R_E}$ ($k_x x \sim 0.3$), hence is largely negligible at

306   further distances. The horizontal and total magnetic field magnitudes on the ground have

307   RMS values 1.2–2× and 1–1.7× those of the incident/reflected waves, i.e. only includ-

308   ing the magnetopause currents (when all current systems are considered above the iono-

309   sphere the ratios become $\sim 0.6\times$). Thus despite infinitesimal latitudinal width of FACs,

310   the ionosphere might not screen the surface mode from the ground as suggested by Kivel-

311   son & Southwood (1988). The ionospheric screening effect goes as $\exp\left(-kh_{isp}\right)$, where

312   h_{isp} is the ionospheric altitude, meaning that the small latitudinal wavenumbers are not

313   suppressed. While in the y-direction there is only one wavenumber k_y present, in the x-

314   direction the delta function in the current has equal Fourier amplitudes at all wavenum-

315   bers, thus small total wavenumbers $k = \sqrt{k_x^2 + k_y^2}$ in this superposition may be trans-

316   mitted to the ground. This highlights the need when applying the Hughes & Southwood

317   (1976) formulae for non-plane waves to use Fourier (or spherical harmonic) decompo-

318   sition, rather than simply measures of spatial amplitude extent (cf. Ozeke et al., 2009).

319   Finally, we quantify the extent to which each current system controls the total ground

320   magnetic field through computing the Coefficient of Determination (see Appendix A).

321   Since the pattern propagates, integration in time is equivalent to spatially along y. This

322   is performed at each distance x away from the OCB. On average the Hall currents ex-

323   plain 92% of the variance in the ground field across all components (further statistics are

324   given in Table S1), hence they still exhibit overwhelming control within the model.

325   We find that changing wavelengths and ionospheric conductivities in this model lead

326   to qualitatively similar results, but leave a full parameterisation to future work. How-

327   ever, we briefly discuss the likely effect of introducing a finite boundary thickness, which

328   will change the surface magnetopause currents used into volume currents. Figure 1e con-

329   siders a linear Alfvén speed variation between the two half-spaces (black) as in Chen &

330   Hasegawa (1974), comparing this to the infinitesimal boundary used thus far (grey). South-

331   wood & Kivelson (1990) note that in an azimuthally-uniform box model, FAC sources

332   in a cold plasma are proportional to the product of: (1) the gradient in squared Alfvén

333   speed; and (2) azimuthal derivative of the compressional magnetic field signal. The fig-

334   ure shows while in the infinitesimal case term (1) is non-zero coincident with the OCB,

335 for a finite thickness boundary term (1) instead peaks at the inner edge of the magne-

336 topause layer due to the high magnetospheric Alfvén speed. This is no longer coincident

337 with the OCB, which will be located somewhere within the boundary. Considering term (2),

338 outside of the boundary layer the surface mode's compressions must decay exponentially

339 with distance from the magnetopause within the two half-spaces. The sign of the com-

340 pressions must also reverse within the boundary layer itself. These two facts necessitate

341 that term (2) exhibit peaks near the boundary layer edges (see also Figure 1 of A22).

342 Combining both terms suggests surface mode FACs are largest near the inner edge of

343 the magnetopause. This conclusion holds within a box model for more complicated tran-

344 sitions or if thermal effects are included (Itonaga et al., 2000).

3 Global Simulation

346 We now employ a global coupled MI simulation to better understand magnetopause

347 surface modes' potential auroral, ionospheric, and ground magnetic signatures within a

348 more representative environment.

3.1 Overview

350 The Space Weather Modeling Framework (SWMF; Tóth et al., 2005, 2012) is used

351 on NASA's Community Coordinated Modeling Center (CCMC). This includes BATS-

352 R-US (Block-Adaptive-Tree-Solarwind-Roe-Upwind-Scheme; Powell et al., 1999) global

353 MHD magnetosphere, which is run at high-resolution ($^1/_8$–$^1/_{16}$ R_E in the regions consid-

354 ered), coupled to an electrostatic thin-shell ionosphere (Ridley et al., 2004), where the

355 same uniform conductances as in section 2 are used. The run, which was previously pre-

356 sented by A21 and A22 (based on H15), simulates the magnetospheric response to an

357 idealised solar wind pressure pulse under northward IMF. Full setup details are in Ta-

358 ble S2.

359 Here we summarise salient results from the BATS-R-US simulation. H15 showed,

360 following an initial transient response, the pulse excites damped monochromatic com-

361 pressional waves near-globally with 1.8 mHz frequency. Amplitudes of these waves de-

362 cay with distance from the magnetopause, with a phase reversal across the boundary.

363 The authors concluded these oscillations could only be explained by MSE. A21 found

364 that across most of the dayside, magnetopause displacements showed little azimuthal phase

variation. Indeed, the surface waves are stationary between 09–15h Magnetic Local Time (MLT), despite non-negligible magnetosheath flows being present. They demonstrated this is achieved by the time-averaged Poynting flux inside the magnetosphere surprisingly pointing towards the subsolar point, balancing advection by the magnetosheath flow such that the total wave energy flux is zero. Outside of this region, waves are seeded tailward at the dayside natural frequency and grow due to KHI. A22 reported the magnetospheric velocity polarisation's handedness in the stationary region (Earthward of the surface mode's turning point) was also reversed from that typically expected, which was found only in the tailward propagating regions. While associated magnetic field polarisations can be reversed by the field geometry near the cusp, Earthward of each field line's apex both polarisations are the same. A consequence of these results is MSE must have spatially varying wavenumbers. Across the dayside the system response is large-scale ($k_\perp \ll k_\parallel$) and thus insensitive to the flow. Since fluctuations seeded downtail from the dayside have fixed frequency in Earth's frame, in the flanks this results in the Doppler effect (i.e. $\omega' = |\omega - \mathbf{k} \cdot \mathbf{v}_{msh}| \approx k_\perp v_{msh}$ due to the significant flow velocities) imposing shorter wavelengths along the magnetopause of $\sim 10\,\mathrm{R_E}$. Normal to the magnetopause, phase fronts inside the dayside magnetosphere slowly propagate towards the boundary ($\ll v_A$). The authors argued this results from the magnetosonic dispersion relation when both compressibility and damping of the surface wave are taken into account. Finally, the surface mode is shown to couple to MHD body waves where their frequencies match: waveguides were found along the equatorial terminator and outer flanks; FLRs were identified on the equatorial terminator Earthward of the magnetopause and in the magnetotail (A21; A22).

As in those previous studies, in this paper we focus on the MSE response (times $t > 15\,\mathrm{min}$) neglecting the directly-driven transient activity. Perturbations (represented by δ's) from equilibrium (represented by subscript 0's) are extracted by subtracting 40 min LOESS (Cleveland, 1979) filtered data, where outliers were neglected. This removed long-term trends well during the period of interest, with spurious values occurring only before the arrival of the pulse. For the ionosphere and ground, coordinates employ Northward and Eastward horizontal components as well as the vertical/radial direction. In the magnetosphere, an equivalent field-aligned system is used. The field-aligned direction $\hat{\mathbf{B}}_0$ is the 90 min time-average of the LOESS-filtered magnetic field. Other directions are obtained as perpendicular projections of the local spherical polar unit vectors ($\hat{\boldsymbol{\theta}}$ for co-

latitude and $\hat{\phi}$ for azimuth). Specifically, the perpendicular Northward direction is $\hat{\boldsymbol{\mathcal{N}}}_\perp = -\left(\hat{\boldsymbol{\theta}} - \hat{\mathbf{B}}_0 \cdot \hat{\boldsymbol{\theta}}\right) / \left|\hat{\boldsymbol{\theta}} - \hat{\mathbf{B}}_0 \cdot \hat{\boldsymbol{\theta}}\right|$ and perpendicular Eastward is $\hat{\boldsymbol{\mathcal{E}}}_\perp = \left(\hat{\boldsymbol{\phi}} - \hat{\mathbf{B}}_0 \cdot \hat{\boldsymbol{\phi}}\right) / \left|\hat{\boldsymbol{\phi}} - \hat{\mathbf{B}}_0 \cdot \hat{\boldsymbol{\phi}}\right|$. All Fourier analysis is computed between $t = 15\text{–}90\,\text{min}$ and limited to frequencies $1.0\text{–}2.1\,\text{mHz}$, with results being integrated over this band.

3.2 Validity

We must assess the validity of using this simulation to predict auroral, ionospheric, and ground magnetic signatures of magnetopause surface modes. This is based on how MI-coupling is treated, as outlined in Ridley et al. (2004) and depicted in Figure 2a. Global MHD models are not able to simulate down to ionospheric altitudes, e.g. since high Alfvén speeds slow down computations, thus magnetospheric boundary conditions are imposed on the plasma and fields further out ($r = 2.5\,\text{R}_\text{E}$ here). This leaves a gap region between the magnetosphere inner boundary and the thin-shell ionosphere ($110\,\text{km}$ altitude) which is not simulated. MI-coupling occurs a few grid cells radial of the magnetosphere inner boundary ($r = 3\,\text{R}_\text{E}$), where FACs are mapped and scaled through the gap region to the ionosphere along dipole field lines. This means equatorward of $\pm 55°$ magnetic latitudes there are no gap region FACs, hence we limit all analysis to poleward of $60°$. The ionosphere model solves for the electric potential via current continuity with a given conductance pattern, similarly to section 2, which yields ionospheric electric fields, currents, and velocities. The potential is mapped back to the magnetospheric inner boundary, setting the electric field and velocity there also.

As highlighted by Kivelson & Southwood (1988) and indicated in Figure 2a, compressional and shear MHD waves will affect the ionosphere differently due to their different currents. Shear modes exhibit FACs, hence coupling between the magnetosphere and ionosphere will occur, which in simulations will be performed by the current mapping. In contrast, compressional modes have only perpendicular currents and so no current is expected to flow between the magnetosphere and ionosphere. Purely compressional waves result in no significant ionospheric effects, which will be true in simulations also. Therefore, the ionospheric response to incident ULF waves should be reliable.

Potential issues, however, arise when considering ground magnetic field calculations. These are computed by Biot-Savart integration of all current systems: ionospheric Pedersen and Hall currents; those throughout the magnetosphere domain; and gap region

FACs (Yu et al., 2010; Rastätter et al., 2014). Because the MI-interface in simulations is much further away than in reality, perpendicular currents at this interface will make much smaller contributions than they would otherwise due to the increased distance. FACs, on the other hand, are unaffected as they can traverse the gap region. This is illustrated in Figure 2a and could affect both types of MHD waves, though likely more acutely for compressional modes.

We first investigate the amplitudes of compressional and shear modes via the curl and divergence of the electric field perturbations as before. Due to available model outputs on the CCMC, these are calculated via

$$(\nabla \times \delta \mathbf{E})_\parallel = -\frac{\partial}{\partial t} \delta B_\parallel = i\omega \delta B_\parallel \tag{6}$$

for the compressional mode, and

$$\nabla \cdot \delta \mathbf{E} = \delta \left[\nabla \cdot (\mathbf{B} \times \mathbf{v})\right] = \delta \left[\mu_0 \mathbf{j} \cdot \mathbf{v} - \mathbf{B} \cdot \mathbf{\Omega}\right] \tag{7}$$

for the shear mode, where $\mathbf{\Omega} = \nabla \times \mathbf{v}$ is the vorticity. Figure 2b–d shows Fourier wave amplitudes, along with their ratio, for a near-equatorial plane ($z_{GSM} = 2\,\mathrm{R_E}$). At the magnetopause, the OCB is shown as the black solid line and the magnetopause inner edge as the dashed line, which has been manually identified based on the background current, Alfvén speed, and velocity polarisation (A22) and fitted to a polynomial with local time. The large (e.g. $\sim 1.5\,\mathrm{R_E}$ at noon) boundary width in the simulation is a consequence of MHD being unable to resolve small gyroradius scales that dictate the 400–1000 km thickness of the real magnetopause (Berchem & Russell, 1982). Panel b demonstrates compressional mode amplitudes are generally largest near the magnetopause and decay slowly across the magnetosphere with distance from the boundary. Panel c shows shear wave amplitudes exhibit strong peaks inside the boundary layer, consistent with Plaschke & Glassmeier (2011), both at the inner edge and OCB. Away from these peaks, the amplitude falls off much more quickly than in the compressional mode. However, shear amplitudes remain larger than compressional ones almost throughout the equatorial magnetosphere, as indicated by the ratios in panel d. Since dayside FLR frequencies in the simulation are much larger than the observed waves (A22), we conclude the large shear amplitudes are due to non-resonant coupling between the compressional and shear modes. This occurs due to the inhomogeneous Alfvén speed and curvlinear magnetic geometry present (e.g. Radoski, 1971), resulting in a single wave that has mixed properties of both.

458   The same quantities are also shown at $r = 3.5\,\mathrm{R_E}$, near the simulation MI-interface,

459   in Figure 2e–g, where these have been projected along dipole field lines to the northern

460   hemisphere ground. The OCB is found to occupy a small area around the displayed black

461   dot, indicating a mostly closed magnetosphere as has been seen in extended northward

462   IMF simulations previously (Song et al., 2000; Zhang et al., 2009). The magnetopause

463   inner edge maps to latitudes equatorward of the OCB. Compressional mode amplitudes

464   (panel e) are significantly weaker near the MI-interface, in agreement with the expected

465   standing structure (Plaschke & Glassmeier, 2011). They appear constrained to regions

466   equatorward of the magnetopause inner edge and mostly to the dayside. Shear mode am-

467   plitudes (panel f) exhibit strong ridges on both flanks which are well-aligned with the

468   inner/equatorward edge of the magnetopause, along which the amplitudes grow with MLT

469   away from noon. Isolated peaks also occur equatorward of the inner edge on the termi-

470   nator, corresponding to the FLRs identified by A21. Notably no clear peak occurs at the

471   OCB. At $r = 3.5\,\mathrm{R_E}$ the ratio of the shear to compressional mode amplitudes are even

472   greater than at $z_{GSM} = 2\,\mathrm{R_E}$ (panel g), indicating again the mixed properties of the

473   wave.

474   The dominance of shear wave amplitudes over compressive suggests simulation re-

475   sults should be reliable. However, it is currents which are more crucial. Therefore, pan-

476   els h–m display Fourier amplitudes for the perpendicular and parallel currents (and their

477   ratios) at the same locations. Reassuringly the two components have similar patterns

478   to the two wave modes. In particular, at $r = 3.5\,\mathrm{R_E}$ FACs peak along the magnetopause

479   inner/equatorward edge and at the discrete FLRs. While at $z_{GSM} = 2\,\mathrm{R_E}$ perpendic-

480   ular and parallel currents are generally of similar magnitude, at the MI-interface FACs

481   dominate poleward of ~ 65–$70°$ latitudes (though the current ratio is not as large as that

482   for mode amplitudes). Consequently, as perpendicular currents are small compared to

483   FACs where MI-coupling is performed, Biot-Savart integration will be reliable in esti-

484   mating ground magnetic field signals at high latitudes.

3.3 Optical aurora

486   FACs associated with FLR can result in periodic optical auroral forms (Greenwald

487   & Walker, 1980; Samson et al., 1996; Milan et al., 2001). Upward FACs at the ionosphere

488   are carried by precipitating electrons that may, if sufficiently energetic, cause auroral emis-

489   sion, whereas regions of downward FACs appear relatively darker. Given we have demon-

strated surface modes also exhibit FACs, it is worth exploring their potential auroral signatures.

As shown in panels i and l of Figure 2, oscillatory FACs associated with the surface mode peak at the inner edge of the magnetopause rather than the OCB. This is difficult to intuit theoretically within a realistic magnetosphere (Southwood & Kivelson, 1991; Itonaga et al., 2000), especially since the simplifying assumption of wave scales being smaller than changes in background conditions cannot be made (A22). Nonetheless, the result is in agreement with the box model prediction of section 2. Movie S1 (left) shows perpendicular velocity perturbations near the magnetospheric equator. While near the subsolar point motion is largely normal to the boundary, away from the Sun-Earth line vortical structure emerges near the magnetopause, particularly at the flanks. The clearest structures have vortex cores Earthward of the OCB, corresponding to the inner surface mode (Lee et al., 1981; A22). These are associated with significant field-aligned vorticity, though this quantity is prevalent throughout the magnetosphere (middle). In a uniform plasma only Alfvén waves exhibit parallel vorticity, hence this results from non-resonant coupling between the compressional and shear modes. On the dayside magnetosphere, the vorticity exhibits phase structure which has shorter normal scales ($\sim 6\,\mathrm{R_E}$) than transverse ones (the entire morning/afternoon sector). There is also slow ($\ll v_A$) phase motion towards the boundary. Since all signals' amplitudes decay with distance from the magnetopause inner edge, the vorticity appears to grow as its phase fronts travel towards the boundary. These features are very similar to those reported in A21 for the compressional magnetic field, explained as the result of surface wave damping. We also note these boundary normal wavelengths are much larger than those expected for field line resonance, since the large gradients in FLR frequencies (A22) suggest scales $< 1\,\mathrm{R_E}$ (Southwood & Allan, 1987). In contrast to the dayside, tailward of approximately the terminator, transverse wavelengths shorten to $\sim 10\,\mathrm{R_E}$ and phase motion appears predominantly tailward. Vorticity magnitudes in the flanks are significantly larger than on the dayside due to KHI-amplification and the shorter scales. We note that coupling of MSE to body modes, such as waveguides or FLR, has been shown to occur in these regions (A21), hence care should be taken in interpreting features as purely due to the surface mode. Finally, FAC patterns (right) are very similar to the vorticity, as expected theoretically by Southwood & Kivelson (1991). Thus, magnetopause surface modes may

exhibit FACs not just within the boundary, as in simple box models, but throughout the magnetosphere.

Based on these results near the equatorial plane, we expect that FAC structures at the MI-interface due to the surface mode consist of large-scale (compared to those of Alfvén waves) poleward moving forms on the dayside. Indeed, this can be seen in Movie S2 (left) which shows the ionospheric FAC input. On the dayside, FAC latitudinal wavelengths are $\sim 10°$ ($\sim 1000\,\mathrm{km}$ in the ionosphere), larger than expected for FLRs in this region. The structures propagate polewards at $1.4°\,\mathrm{min}^{-1}$ (or equivalently $2.6\,\mathrm{km\,s}^{-1}$), growing in amplitude with their phase motion until they peak at the projection of the magnetopause inner/equatorward edge (as demonstrated in Figure 2i). The azimuthal extent of these waves is likely a function of the driver, hence solar wind excited surface waves like in the simulation should exhibit more extended FACs than those due to most foreshock transients (Sibeck et al., 1999) or magnetosheath jets (Archer et al., 2019). In the simulation, we find that outside of the 09–15h MLT stationary region FAC structures propagate principally towards the tail, forming periodic structure along the projection of the boundary's inner/equatorward edge. While on the dayside structures appear azimuthally stationary, like the surface waves in the magnetosphere, the tailward propagating behaviour of the eigenmode outside the stationary region causes the FACs to bifurcate at the boundary between the two regimes during their poleward phase motion. This results in more complex structure than simply a (spherical) harmonic wave.

We conclude that magnetopause surface modes may be expected to have optical auroral signatures somewhat similar to FLRs. These consist of periodic brightenings with latitudinal arc widths of $\sim 5°$ that propagate polewards at slow speeds of ~ 1–$2°\,\mathrm{min}^{-1}$ (~ 2–$4\,\mathrm{km\,s}^{-1}$). The intensity of these periodic aurorae should amplify with their phase motion, peaking not at the OCB as had been thought before (O. Kozyreva et al., 2019), but equatorward of it at the projection of the magnetopause inner edge. In our simulation the OCB and magnetopause inner/equatorward edge are highly separated, about $\sim 7°$ in latitude at noon. However, this is merely due to the large magnetopause thickness. We estimate realistic separations between the OCB and magnetopause inner/equatorward edge to be ~ 1–$2°$ for the driving conditions considered. This is based on the latitudinal difference in the simulation of traced footpoint locations from field lines separated by the boundary widths reported by Berchem & Russell (1982). Thus dayside auroral brightenings associated with surface modes, when visible due to the time of day / sea-

555 son, might consist of poleward moving arcs that intensify towards and peak a few de-

556 grees equatorward of an OCB proxy. Further into the flanks, auroral brightenings may

557 form clear periodic structure along the projection of the boundary inner/equatorward

558 edge, which will principally propagate azimuthally. KHI will likely make these auroral

559 features generally stronger on the flanks. The auroral signatures of surface modes might

560 be distinguished from FLR by their higher latitude location, lower frequency, and larger

561 latitudinal extent. However, we make no claims here on the character, colour, or taxon-

562 omy of such potential auroral signatures, since these cannot be easily predicted by MHD

563 simulations. It also remains to be seen whether these auroral signals can be extracted

564 from background emissions under different activity levels.

3.4 Ionospheric convection

566 Perturbation convection patterns are shown in Figure 3a–d as streamline snapshots

567 over approximately half a cycle, and in Movie S2 as animated quivers. These reveal on

568 the dayside large-scale convection vortices are present, which circulate the FAC maxima

569 (bold lines in Figure 3a–d). Vortices are clockwise for upward currents and anticlock-

570 wise for downward, in agreement with section 2. Interestingly, the vortex cores are lo-

571 cated at $\sim 09h$ and $\sim 15h$ MLT, i.e. the transition between stationary and propagat-

572 ing magnetopause surface waves. Like the FACs, dayside vortices have shorter latitudi-

573 nal scales than longitudinal. At the lower latitudes considered though, vortices appear

574 more spread out in the equatorward direction. This is likely because successive FAC struc-

575 tures become weaker towards the equator, making the ionospheric response more like in

576 the box model. Since dayside FAC structures move polewards and grow in strength to-

577 wards the magnetopause inner/equatorward edge, the convection vortices travel pole-

578 wards and exhibit increases in speed up to this point also. Thus poleward-moving se-

579 quencies of TCVs on the dayside may be a clear ionospheric signature of MSE. These

580 are unlike typically reported isolated / pairs of TCVs associated with the direct impacts

581 of solar wind / foreshock pressure pulses or flux transfer events, which exhibit only tail-

582 ward motion (Friis-Christensen et al., 1988; Sibeck, 1990), suggesting this phase motion

583 could be a potential diagnostic for identifying MSE in ground-based data.

584 Figure 3e–f shows Fourier amplitudes of the two ionospheric velocity components.

585 Around noon signals are mostly North-South, like the radial motions exhibited in the

586 magnetosphere in this sector (A21; A22). Amplitudes peak at the magnetopause inner/equatorward

587 edge, just like the FACs. However, the amplitude of the East-West component increases

588 significantly away from noon towards the flanks. This is most evident in panel g, which

589 displays polarisation ellipses derived from the Fourier transforms (as outlined in A22).

590 Away from noon the ellipses' orientations rotate away from the North-South direction

591 and the magnitude of their ellipticity increases. Ionospheric velocity polarisations show

592 consistent handedness with those out in the equatorial magnetosphere (A22), in partic-

593 ular a reversal is present either side of the transition between stationary and propagat-

594 ing surface waves. Panels h–i indicate phases and propagation directions for the veloc-

595 ity components, which are quite different from one another. There is little phase vari-

596 ation in the North-South component on the dayside, with only slight poleward phase mo-

597 tion in the stationary region. This reflects the large-scale periodic North-South motion

598 associated with the surface waves that is clear from Movie S2. In constrast, the East-

599 West component exhibits much larger gradients in phase latitudinally across the day-

600 side. These differences are due to a combination of the vortices' larger longitudinal scales

601 compared to latitudinal along with the poleward motion of these vortices. Azimuthal phase

602 variation is introduced in the tailward propagating regime for both velocity components,

603 though is clearest in the North-South direction.

604 The finite ionospheric conductivity causes significant spreading out of patterns caused

605 by localised FACs. Therefore, in the above we have focused on the dayside as we know

606 an FLR is also present at lower latitudes on the terminator. Figure 3e–f shows that at

607 the terminator two amplitude peaks on each flank are present in both components. One

608 of these is near the magnetopause inner boundary, whereas the other is located near the

609 FLR location. There is clearly significant spreading longitudinally of the FLR-related

610 amplitude structures, meaning that ionospheric convection patterns in general consist

611 of a complex superposition of those due to the surface mode and its coupled FLR(s). Only

612 in the vicinity of noon will the ionospheric response be dominated by that purely due

613 to the surface mode.

614 Figure 4 shows potential ionospheric Doppler radar observations, emulating typ-

615 ical range-time plots. These show the time variation of the North-South velocity per-

616 turbations with latitude for nearby local times. Figure 4a corresponds to the dayside,

617 which clearly shows in each panel periodic oscillations in the ionospheric velocity that

618 exhibit poleward phase motion and peak in amplitude near the projection of the mag-

619 netopause inner boundary (grey dashed line). Comparing the panels indicates there is

620 little phase propagation in MLT since the surface waves are stationary, again unlike typ-

621 ical tailward TCVs. Figure 4b corresponds to the flanks, highlighting the increased com-

622 plexity of the signal away from noon. Nonetheless, some similar features to the dayside

623 are seen. While the amplitude does maximise near the magnetopause inner boundary,

624 a secondary amplitude maximum is present at lower latitude associated with the termi-

625 nator FLR. All of these patterns in the flank exhibit tailward phase propagation when

626 comparing panels.

3.5 Ground magnetic field

628 Ground magnetic field perturbations were computed using the CalcDeltaB post-

629 processing tool (Rastätter et al., 2014), performed in SM coordinates due to the idealised

630 model setup. We compare these to the magnetic field signals near the MI-interface. Both

631 are shown in Movie S3.

632 Figure 5a–c show the wave amplitudes and polarisations in the magnetosphere near

633 the MI-interface. On the dayside perturbations are predominantly North-South oriented

634 and maximise at the magnetopause inner/equatorward edge. In contrast, as shown in

635 panels d–f, on the ground the magnetic field is mostly in the East-West direction. The

636 movie shows these East-West signals are coherent across most of the dayside, converg-

637 ing/diverging from the ionospheric vortex cores at $\sim 09h$ and $\sim 15h$ MLT. This is un-

638 like toroidal mode Alfvén waves, some of the most intensively studied ULF waves, which

639 are aligned mostly North-South on the ground. The Fourier amplitude maps at the MSE

640 frequency in Figure 5 for the ground horizontal components resemble those in the mag-

641 netosphere for the other component, i.e. that at right angles. Ground signals are of sig-

642 nificantly greater amplitude than in the magnetosphere. While this is similar to the box

643 model, in the simulation this will partly be due to the scaling of FACs across the gap

644 region with B_0. Ground magnetic field amplitudes also appear more extended than above

645 the ionosphere. This is due to the spreading of currents in the ionosphere by the finite

646 conductance, as discussed previously, as well as spatial integration of these ionospheric

647 currents (Plaschke et al., 2009). The handedness of wave polarisations above and below

648 the ionosphere are largely the same. Notable differences occur at the lowest latitudes shown,

649 where the ground magnetic field is less reliable. Generally we see the ground magnetic

650 field has greater ellipticity than in the magnetosphere, likely due to finite ionospheric con-

651 ductance spreading out the currents' vortical patterns.

The time-averaged rotation angle from the magnetosphere to the ground was calculated for each point using the Fourier method outlined in Appendix B. Over the region depicted, this had a mean and standard deviation of $89\pm21°$. Note the magnetic field near the MI-interface does not include contributions from ionospheric Pedersen and Hall currents, hence is associated with the incident/reflected waves only. We find in agreement with the box model that the ionosphere rotates surface wave magnetic fields by close to $90°$, though significant spread in this angle occurs. Unlike in section 2, however, we found no systematic spatial ordering of the rotation angle. This may be because in the simulation FACs are not confined to within the boundary and move poleward. We again compute the Coefficient of Determination at each point to quantify the contribution of different current systems to the total ground magnetic field. Here this is done using Fourier methods, as outlined in Appendix A. As in the box model, it is Hall currents which dominate the ground field, hence why the rotation angle is close to $90°$. However, on average Hall currents explain only 43% of the variance across all components – much smaller than in the simple box model. Tabel S1 demonstrates, however, that the other current systems (excluding Hall) and their combinations are not significant predictors of the ground field. Therefore, the total variance on the ground must be a complex superposition of many current systems, including most notably Hall currents.

Movie S3 also shows the vertical component of the ground magnetic field. Qualitatively this somewhat resembles the FACs, in line with predictions from the box model. However, Figure 5g shows towards the flanks, unlike the FACs, the vertical field amplitudes peak at lower latitudes than the magnetopause inner/equatorward boundary. At the terminator the peak corresponds well with the FLRs. Therefore, it appears that the FLR is dominating the vertical field perturbations on the ground, relative to surface mode, across a wide local time range. Vertical field amplitudes are generally greater than the horizontal ones only in the vicinity of their peaks. Close to noon, however, the vertical field is weak and only becomes significant at $\sim 09h$ and $\sim 15h$ MLT, the locations of dayside ionospheric vortex cores.

Figure 6 shows stacked time-series of a latitudinal chain of virtual ground magnetometers located close to noon, where effects of the FLR are small. These demonstrate poleward phase motion of the ground magnetic field in all three components, unlike ground magnetometer observations of typical isolated / pairs of TCVs which show predominantly tailward motion (e.g. Friis-Christensen et al., 1988). Like with the ionospheric velocity

though, this phase motion is slightly different for all three components. The amplitude variation (blue lines) is quite broad for all three components. While the vertical component appears to peak at the magnetopause inner/equatorward edge, the East-West component's maximum appears shifted slightly poleward of this location and the North-South component has a rather flat peak. Nonetheless, all three maxima are clearly closer to the magnetopause inner/equatorward edge than the OCB within the simulation. We suggest that all these features could be used as diagnostics for identifying surface modes in ground magnetometer networks.

4 Discussion

4.1 Limitations

In both aspects of this study we have employed uniform ionospheric conductances. This was to understand the surface mode's ground-based signatures in the simplest case. Improved empirical conductance maps typically include effects of solar illumination and/or auroral oval conductance contributions (Ridley et al., 2004). The former exhibit relatively small variations over scales much larger than surface mode wavelengths, hence likely have little effect on the predictions. In contrast, auroral oval Hall conductances can be significantly larger than those outside this region. While these could result in stronger currents within the auroral oval, and thus stronger ground magnetic signals, the sense of FAC closure would likely remain. Hartinger et al. (2017) performed simulations comparing ground field perturbations from a solar wind pressure increase under different conductance models. They found qualitatively similar results for the uniform and solar conductance patterns, but somewhat different amplitude profiles with the auroral pattern.

So far we have treated the ground as a perfect insulator, in line with most past global modelling and observational work (e.g. Samsanov et al., 2015; Tanaka et al., 2020). While some other ULF wave studies have considered the ground to be a perfect conductor (e.g. Hughes, 1974; Hughes & Southwood, 1974; Waters & Sciffer, 2008), neither regime realistically includes contributions from induced telluric currents in the ground. To estimate their likely effect we apply the Complex Image Method (Boteler & Pirjola, 1998; Pirjola & Viljanen, 1998). This places an image current, with the same strength as that in the overhead ionosphere, at a depth of $h_{isp}+2p$ for complex skin depth p. Here we

715 take this skin depth to be

$$p = \frac{1}{\sqrt{i\omega\mu_0\sigma}} \tag{8}$$

716 where σ is the ground conductivity. One can assume a uniform conductivity that is able

717 to capture the spatial variations in the field/currents through a plane wave (Pirjola et

718 al., 2009). For wavelengths $> 200\,\text{km}$ and periods $< 1\,\text{min}$, valid for MSE, this yields

719 values of $\sim 1\text{--}2\,\text{mS}\,\text{m}^{-1}$, in line with ground conductivities for rocky or city areas (Ce-

720 bik W4RNL, 2001). These values along with the simulation MSE frequency result in skin

721 depths of magnitude 190–270 km, much greater than the ionospheric altitude. Given that

722 in both the box model and simulation the ground magnetic field was mostly dictated by

723 Hall currents with large scale sizes, we estimate the ground magnetic fields from telluric

724 currents by assuming an infinite line current in the ionosphere (Boteler & Pirjola, 1998).

725 This predicts horizontal ground magnetic field perturbations are amplified by 18–24%

726 and vertical fields reduced by 3–6% due to the induced ground currents. Phase changes

727 are negligible ($< 7°$). These are relatively small contributions due to the low $1.8\,\text{mHz}$

728 frequency of the surface mode, since lower frequencies are less effective at inducing tel-

729 luric currents for a given amplitude. In contrast, higher frequency ULF waves of $10\text{--}100\,\text{mHz}$

730 are predicted to change the horizontal field by 40–70%. We also note that near oceans,

731 the high $5\,\text{S}\,\text{m}^{-1}$ conductivity of salt water likely renders all ULF waves' ground signa-

732 tures greatly affected ($> 90\%$). Future studies could more comprehensively investigate

733 the importance of telluric currents to ground magnetometer signals of surface and other

734 ULF waves.

735 Our brief evaluation of these limitations suggests the use of a wide range of lati-

736 tudes when examining potential observations to these predictions, where overall trends

737 likely persist. On smaller scales, local effects due to varying conditions in the ionosphere

738 and the ground may be more important, which could form the basis of future work.

4.2 Comparison to previous observations

740 Auroral brightenings, ionospheric convection vortices, and ground pulsations are

741 expected from FACs in general. However, mapping observations from the ground out to

742 space is difficult when trying to distinguish surface waves from nearby body waves. We

743 thus limit comparitive discussion to studies that could better constrain ground-based ob-

744 servations.

745   Previous conjugate observations have linked aurorae to surface waves. He et al. (2020)

746   suggested sawtooth aurorae, large-scale undulations along the equatorward edge of the

747   diffuse aurora, may be the optical atmospheric manifestation of plasmapause surface waves.

748   During a geomagnetic storm, they showed 1.4 mHz plasmapause surface waves (i.e. with

749   similar frequencies to MSE) in the afternoon-dusk correlated with sawtooth auroral pat-

750   terns near the footpoints of the plasmapause field lines, with wavelengths and propaga-

751   tion speeds of both being in agreement. The authors suggested the modulation of hot

752   plasma by the plasmapause surface mode may have led to particle precipitation, and thus

753   diffuse aurora, via scattering by electron cyclotron harmonic waves. Similarly, Horvath

754   & Lovell (2021) presented two case studies of KHI-waves on the flank magnetopause dur-

755   ing geomagnetic storms, which appeared to excite surface waves on / near the plasma-

756   pause in the hot zone of the outer plasmasphere. During these events, correlated com-

757   plicated sub-auroral plasma flows and large auroral undulations were observed at low Earth

758   orbit. The authors conclude magnetopause surface modes couple, in complex ways, to

759   the inner magnetosphere and auroral zones. Finally, the ground-based study of O. Kozyreva

760   et al. (2019) used observations of the equatorward edge of the red cusp aurora as an op-

761   tical proxy for the OCB following southward IMF turnings. They noted quasi-periodic

762   motion of this boundary in 3 events, which they interpreted as evidence for MSE.

763   Archer et al. (2019) first showed MSE signatures may be present in dayside ground

764   magnetometer data, though unfortunately data was low resolution and had poor spa-

765   tial coverage which limited conclusions. O. Kozyreva et al. (2019) presented data from

766   a near-noon latitudinal chain following impulsive external driving. Short-lived oscilla-

767   tions in the North-South component were found to peak ~ 1–$2°$ equatorward of the op-

768   tical OCB proxy. While the authors attributed this to experimental uncertainty, it is un-

769   clear why this would result in a systematic effect. The offset agrees with our estimates

770   for the inner/equatorward edge of the magnetopause boundary layer, thus could instead

771   be consistent with our results. They also noted poleward phase motion and large ~ 8–$10°$

772   latitudinal scales, both like in our simulation. He et al. (2020) demonstrated ground mag-

773   netic pulsations associated with plasmapause surface waves in the afternoon-dusk sec-

774   tor. A latitudinal magnetometer chain showed clear poleward phase motion, as in the

775   simulation. However, the authors suggest the plasmapause surface wave may have cou-

776   pled to an FLR outside the plasmasphere due to the amplitude and phase structure ob-

777   served, potentially complicating these observations. Finally, Hwang et al. (2022) presented

778 two case studies of KHI-waves and their ground effects. Vortical horizontal field pertur-

779 bations were observed at high latitudes, corresponding to bead-like FACs elongated in

780 the east-west direction like those seen in the simulation flanks.

781   There are some interesting similarities and differences between these magnetopause

782 surface mode results and the classic Sudden Commencement (SC) or, more generally, TCV

783 response of the magnetosphere. These models are generally used to interpret ground-

784 based observations following impulsive solar wind driving, e.g. interplanetary shocks or

785 solar wind pressure pulses, hence warrant further discussion. The Araki (1994) model

786 of SC predicts bipolar variations of the geomagnetic field at polar latitudes due to a global

787 ionospheric twin vortex resulting from pairs of FACs on each of the morning and after-

788 noon sectors. These are similar but larger in scale than typical TCVs. Our simulation

789 results are broadly consistent with this model during the transient period (see Movie S2

790 and Figure 6). The Araki (1994) model, however, does not predict the subsequent pe-

791 riodic oscillations following this transient, which are associated with MSE. This is be-

792 cause it only considers the intensification of magnetopause currents and FACs related

793 to a single ripple on the magnetopause, hence not a surface wave or eigenmode. This is

794 also true of similar TCVs models (e.g. Sibeck, 1990). MHD wave propagation during SC

795 is typically linked to the Tamao (1964a,b) path or cavity/waveguide theory (Kivelson.

796 et al., 1984; Kivelson & Southwood, 1985), where compressional waves couple to FLRs

797 at the location their (eigen)frequencies match. Thus the possible contributions of mag-

798 netopause surface waves has not been considered in past SC observations or modelling

799 (see the review of Fujita, 2019). SC can often be followed by long $\geq 10\,\mathrm{min}$ period waves

800 (e.g. Matsushita, 1962), however, these are rarely discussed. It is therefore possible that

801 ground-based evidence of MSE could be prevalent in past SC observations, with the sub-

802 sequent pulsations either being neglected or misidentified as cavity/waveguide modes and

803 FLR, which are generally not expected to occupy such low frequencies on the dayside

804 (Archer et al., 2015).

805   Overall, our simulation results appear consistent with the few previous reported

806 observational signatures of magnetopause surface waves specifically. However, some as-

807 pects could not be tested with the data presented, motivating the need for both dedi-

808 cated future observational studies and reanalysis of previously examined events in light

809 of this work.

4.3 Implications

The results presented in this paper have potential consequences within the context of space weather, which we briefly comment on.

We have demonstrated magnetopause surface modes are predicted to result in ionospheric currents and electric fields. This offers the possibility that surface wave energy may be dissipated in the ionosphere, like it is for other ULF wave modes (e.g. Glassmeier et al., 1984). Joule heating rates are given by

$$\begin{aligned}
\mathbf{j} \cdot \mathbf{E} \quad &= \tfrac{1}{\Sigma_P} E^2 \\
&= \tfrac{1}{\Sigma_P} \left(E_0^2 + 2\mathbf{E}_0 \cdot \delta\mathbf{E} + \delta E^2 \right)
\end{aligned} \tag{9}$$

where the first term corresponds to the DC equilibrium heating rate and the subsequent terms are associated with pulsations. Recall a uniform Pedersen conductance of $5\,\mathrm{S}$ was used, which is reasonable for sunlit high-latitude regions (cf. Ridley et al., 2004). In the simulation, we integrate these over the entire dayside ionosphere. While the DC rate is $3\,\mathrm{GW}$, we find the maximum pulsation-related rate is $40\,\mathrm{GW}$, occurring during the transient response. The peak dissipation rate during times of confirmed MSE ($t > 15\,\mathrm{min}$) is also significant compared to the background at $0.4\,\mathrm{GW}$ (i.e. 13%). While the inclusion of the KHI-amplification of the surface waves and their coupling to FLRs on the nightside result in the global ionospheric dissipation rates being even greater during MSE times at 25% of the global DC rate, the ionospheric conductances in the nightside hemisphere are less realistic. Overall, these simulation results qualitatively suggest magnetopause surface modes may provide important contributions to ionospheric heating. Further work could quantitatively predict heating rates due to surface waves using a range of more representative ionospheric conditions, improving our understanding of their global significance under different driving regimes.

We also predict that magnetopause surface modes result in oscillatory magnetic fields at Earth's surface. This suggests they could be a source of geomagnetically induced currents driven by geoelectric fields (e.g. Heyns et al., 2021). While geoelectric fields are frequency-dependent with a higher frequency bias relative to the underlying disturbance geomagnetic field (e.g. Boteler & Pirjola, 1998; Pirjola & Viljanen, 1998), distinct Pc5 frequency ULF waves (2–$7\,\mathrm{mHz}$) can result in significant measured geoelectric fields (Hartinger et al., 2020; Shi et al., 2022). Therefore, it is likely that magnetopause surface waves,

839 at either MSE or higher (e.g. intrinsic KHI) frequencies could similarly result in strong

840 geoelectric fields. Modelling this is beyond the scope of this study, as it is known the three-

841 dimensional conductivity structure of Earth is important in accurate characterisation

842 of geoelectric fields (Bedrosian & Love, 2015). Therefore, further study is warranted in

843 assessing whether magnetopause surface modes may be a significant source geoelectric

844 fields and thus geomagnetically induced currents (cf. Heyns et al., 2021; Yagova et al.,

845 2021).

5 Conclusions

847 We have investigated magnetopause surface waves' direct effects on the aurorae,

848 ionosphere, and ground magnetic field through both MHD theory and a global MI-coupling

849 simulation. Our main conclusions are as follows:

850   1. Magnetopause surface modes have associated FACs into / out of the ionosphere,

851   which for a finite thickness boundary maximise at the inner/equatorward edge of

852   the magnetopause rather than the OCB. Non-resonant coupling between the com-

853   pressional and Alfvén modes results in further monochromatic FACs throughout

854   the magnetosphere, hence are unrelated to the Alfvén continuum. The amplitudes

855   of these currents fall off with distance from the magnetopause.

856   2. The normal phase structure reported by A21 in the equatorial magnetosphere due

857   to damping also manifests at the MI-interface as slow ~ 1–$2°\,\mathrm{min}^{-1}$ poleward mov-

858   ing FAC structures. With latitudinal wavelengths of $\sim 10°$ on the dayside, these

859   are large-scale compared to expectations for FLR.

860   3. FACs associated with global MSE are weakest on the dayside, due to smaller bound-

861   ary displacements and azimuthal scales that span the morning/afternoon sector.

862   In the flanks, where the Doppler effect imposes shorter scales and wave pertur-

863   bations are amplified through KHI, strong periodic FACs may be present along

864   the magnetopause inner/equatorward edge.

865   4. We suggest upward FACs associated with surface modes may lead to periodic au-

866   roral brightenings that peak in intensity at the magnetopause inner/equatorward

867   edge. On the dayside, these auroral forms move slowly poleward at ~ 1–$2°\,\mathrm{min}^{-1}$

868   (~ 2–$4\,\mathrm{km\,s}^{-1}$) and occupy large $\sim 5°$ latitudinal bands compared to narrower

FLR-related aurorae. Periodic longitudinal structure will reflect that out at the magnetopause..

5. Ionospheric convection vortices circulate the surface mode's FAC structures. Like the FACs, they are large-scale, poleward moving, and strongest at the magnetopause inner/equatorward edge. The finite conductivity causes ionospheric signals to be more spread out than the FACs.

6. Magnetopause surface modes can also cause ground magnetic field signals. These are largely caused by Hall current vortices, which rotate the magnetic field perturbations from above the ionosphere to the ground by almost $90°$ (though significant non-systematic spread in this rotation angle occurs). Therefore, ground signatures of MSE near noon are strongest in the East-West direction. Oscillations have the same frequency across L-shells, amplitudes peak near the magnetopause inner/equatorward edge, and latitudinal variations are large-scale.

These conclusions provide qualitative predictions for magnetopause surface modes which might be applied to interpreting high-latitude ground-based data. Quantitative predictions require understanding how regional variations in ionospheric and ground conditions affect magnetopause surface modes (and ULF waves more generally). We also note this simulation is North-South and dawn-dusk symmetric due to zero dipole tilt, whereas interhemispheric (e.g. Engebretson et al., 2020; Xu et al., 2020) and dawn-dusk (e.g. Henry et al., 2017) asymmetries in geospace are of great interest in understanding solar wind – magnetosphere – ionosphere coupling. Therefore, how magnetopause surface modes manifest in the magnetosphere, ionosphere, and on the ground when such asymmetries may be present should be ascertained.

Finally, a further potential avenue for remote sensing magnetopause (or even plasmapause) surface modes could be ionospheric Total Electron Content (TEC) data derived from Global Navigation Satellite Systems. Recent work has shown that ULF waves may modulate TEC, yielding periodic oscillations of similar frequency (V. Pilipenko et al., 2014; Watson et al., 2015; Belakhovsky et al., 2016; O. V. Kozyreva et al., 2020; Zhai et al., 2021). While several mechanisms for this have been proposed, overall they remain poorly understood. Future work could use the predicted ionospheric electric fields associated with surface modes to drive height-resolved ionosphere and neutral atmosphere

900   models (Ozturk et al., 2020). This would crucially unveil how the coupled ionosphere

901   – thermosphere – mesosphere system reacts to boundary waves in our magnetosphere.
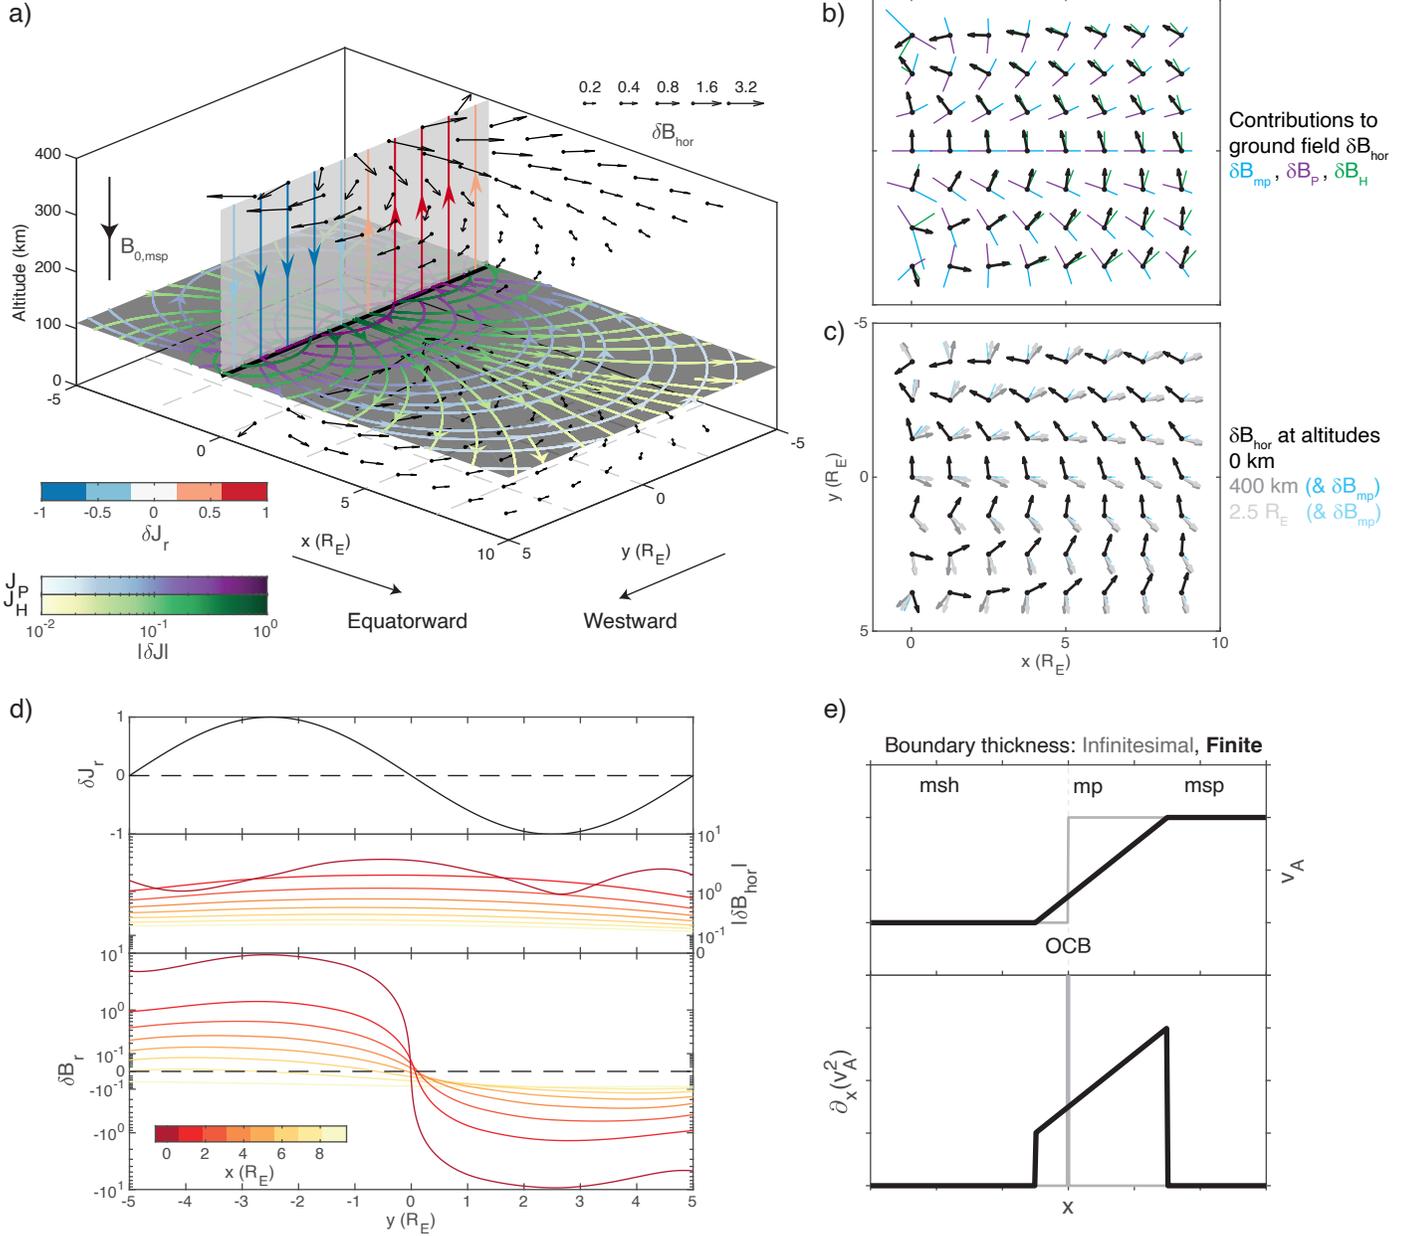

Figure 1: Results from box model theory at the northern ionosphere. (a) Streamlines of the perturbation magnetopause (red/blue), Pedersen (purple) and Hall (green) currents. Horizontal magnetic perturbations on the ground and above the ionosphere are shown as black arrows. (b) Directions and relative magnitudes of the current system contributions to the horizontal ground magnetic field (colours) normalised by the total horizontal perturbation (black) at each position. (c) Horizontal directions of the total magnetic perturbations on the ground (black) and above the ionosphere (grey). Contribution from magnetopause currents for the latter are shown in blue. (d) Magnetopause current variation with azimuth (top) along with the horizontal (middle) and vertical (bottom) ground magnetic perturbations at different equatorward distances (colours). (e) Comparison of Alfvén speed profiles and associated current coupling for an infinitesimally thin (grey) and finite thickness (black) magnetopause.
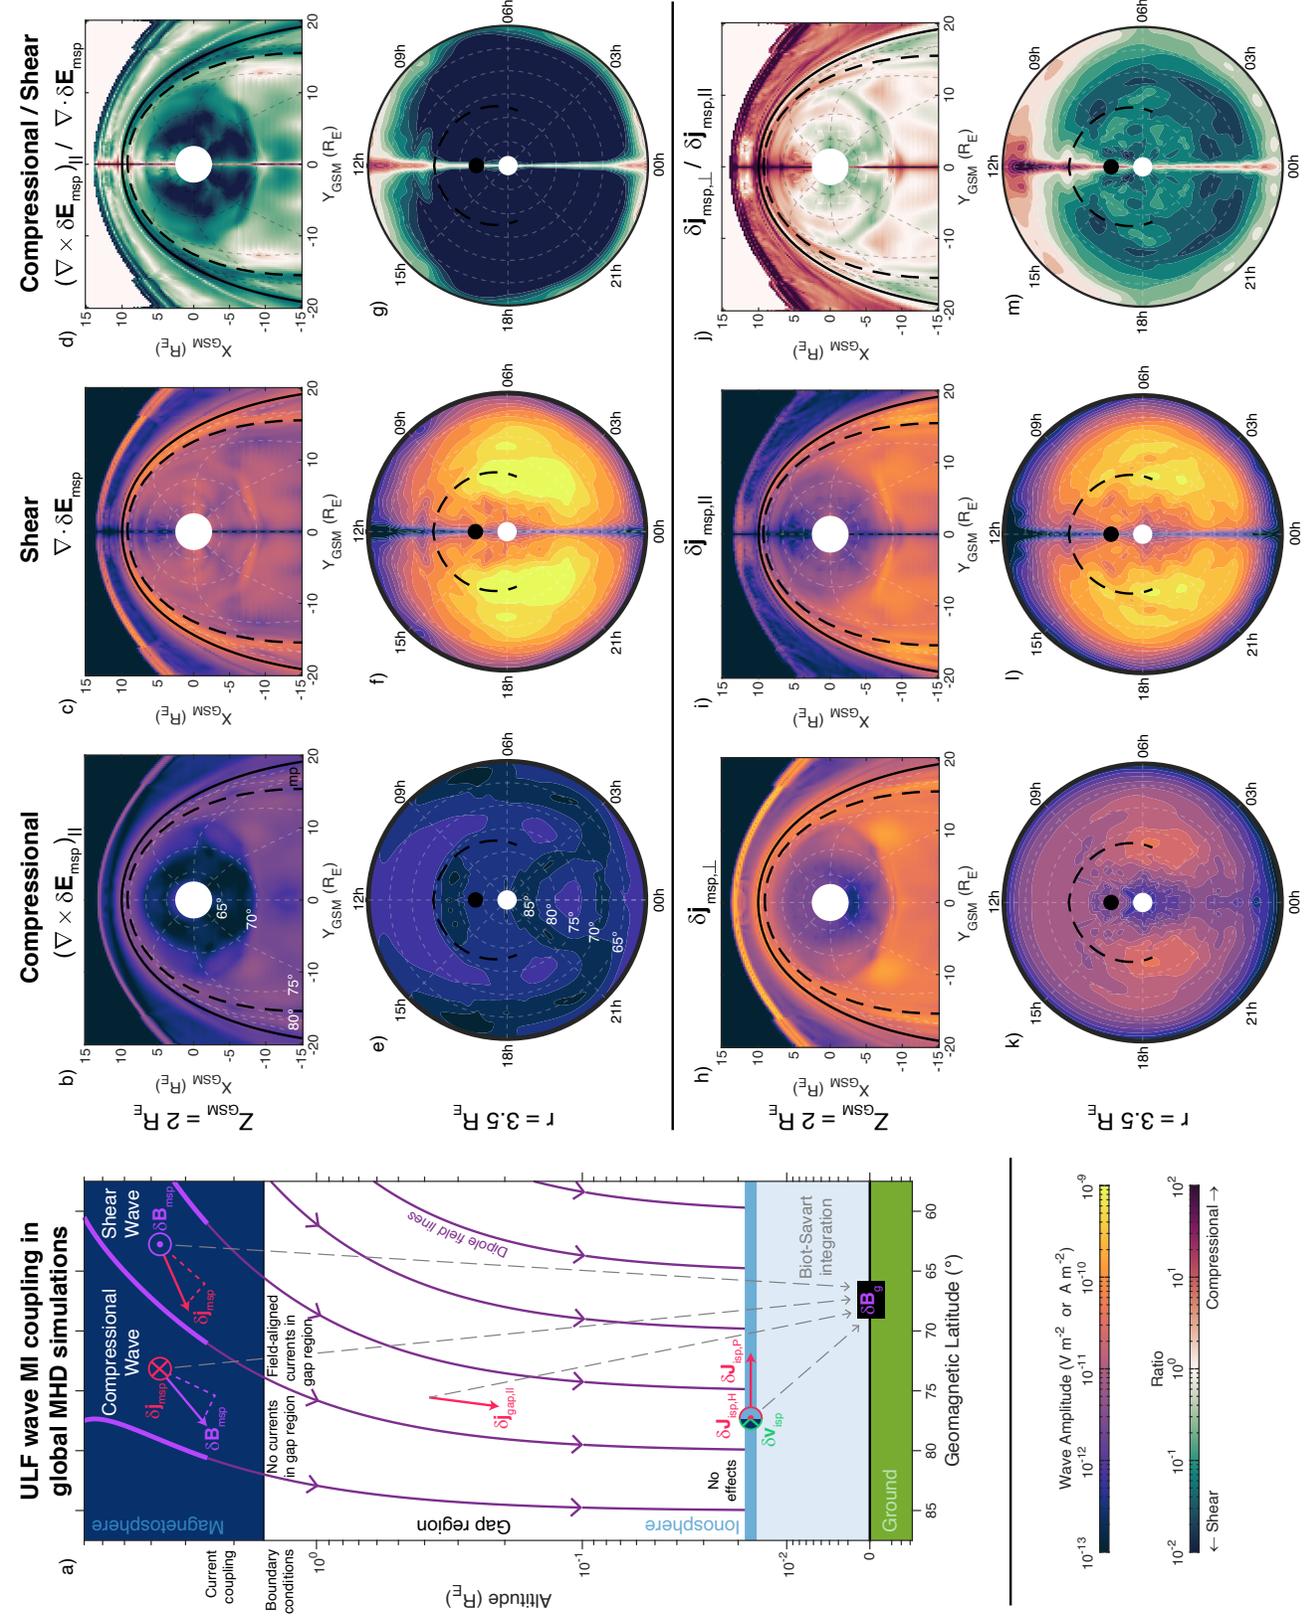

Figure 2: (a) Illustration of magnetosphere–ionosphere coupling within global MHD simulations applied to compressional and shear ULF waves. (b–m) Simulation Fourier maps taken from the $z_{GSM} = 2\,R_E$ near-equatorial plane (b–d,h–j) and at $r = 3.5\,R_E$ near the simulation magnetosphere-ionosphere interface (e–g,k–m), the latter have been projected onto the ground. These show amplitudes of compressional (b,e) and shear (c,f) waves and associated currents perpendicular (h,k) and parallel (i,l) to the background magnetic field. Ratios are also shown (d,g,j,m). Solid black lines indicate the open–closed field line boundary whereas dashed lines indicate the magnetopause inner edge.

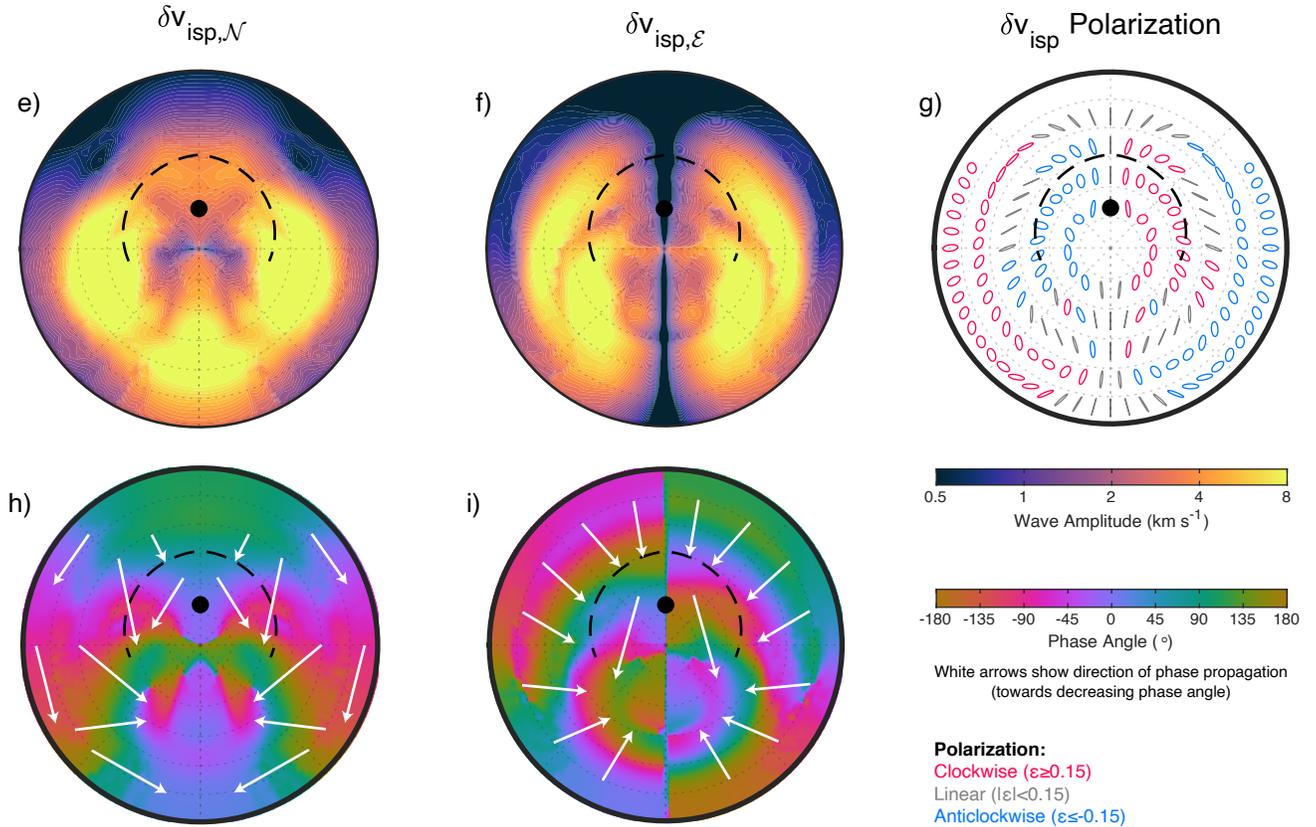

Figure 3: (a–d) Snapshots of ionospheric convection over half an MSE cycle, displaying the velocity magnitude (green) and streamlines (grey). Field-aligned current ridges are also indicated. (e–i) Fourier maps, in a similar format to Figure 2e, of the ionospheric velocity showing perturbation amplitudes (e,f) and phases (h,i) for the North-South (e,h) and East-West (f,i) components. Polarization ellipses are displayed in panel (g), coloured by the sense of rotation.
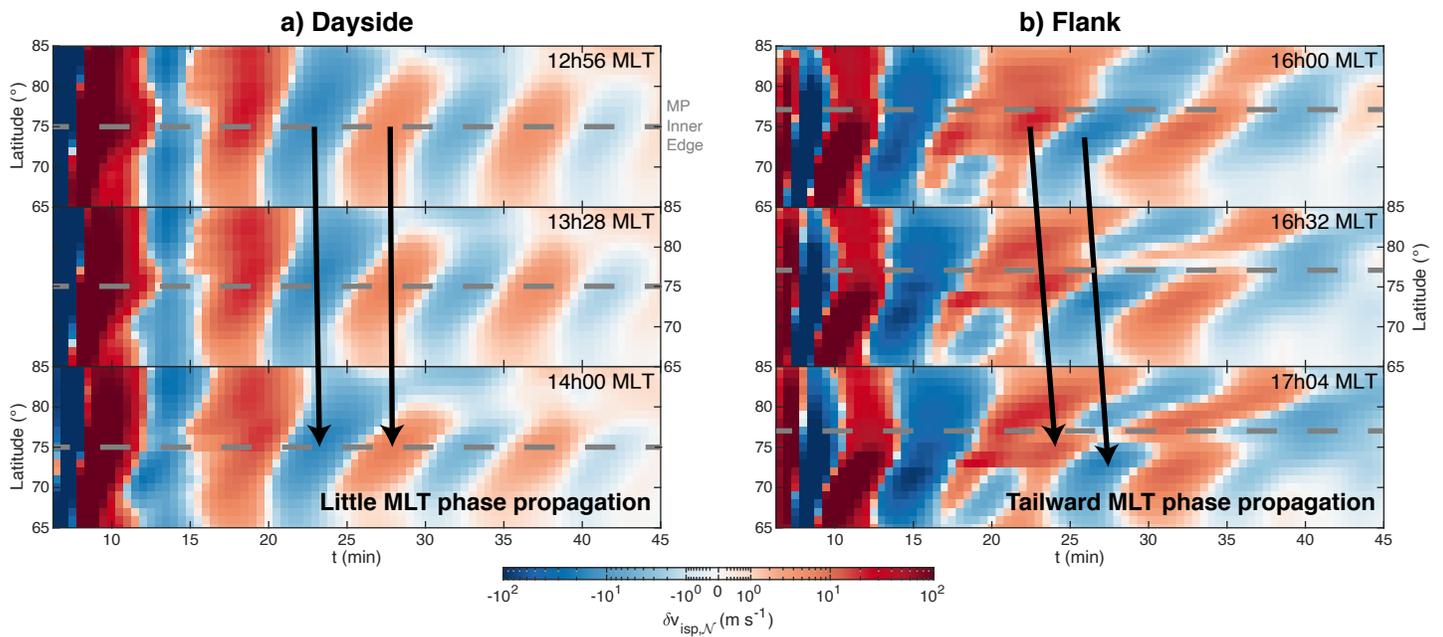

Figure 4: Examples of potential ionospheric Doppler radar observations. Simulation equivalents of range-time plots for adjacent beam directions (local times) are shown for the (a) dayside and (b) flank. The projection of the magnetopause inner edge is also indicated (grey dashed).
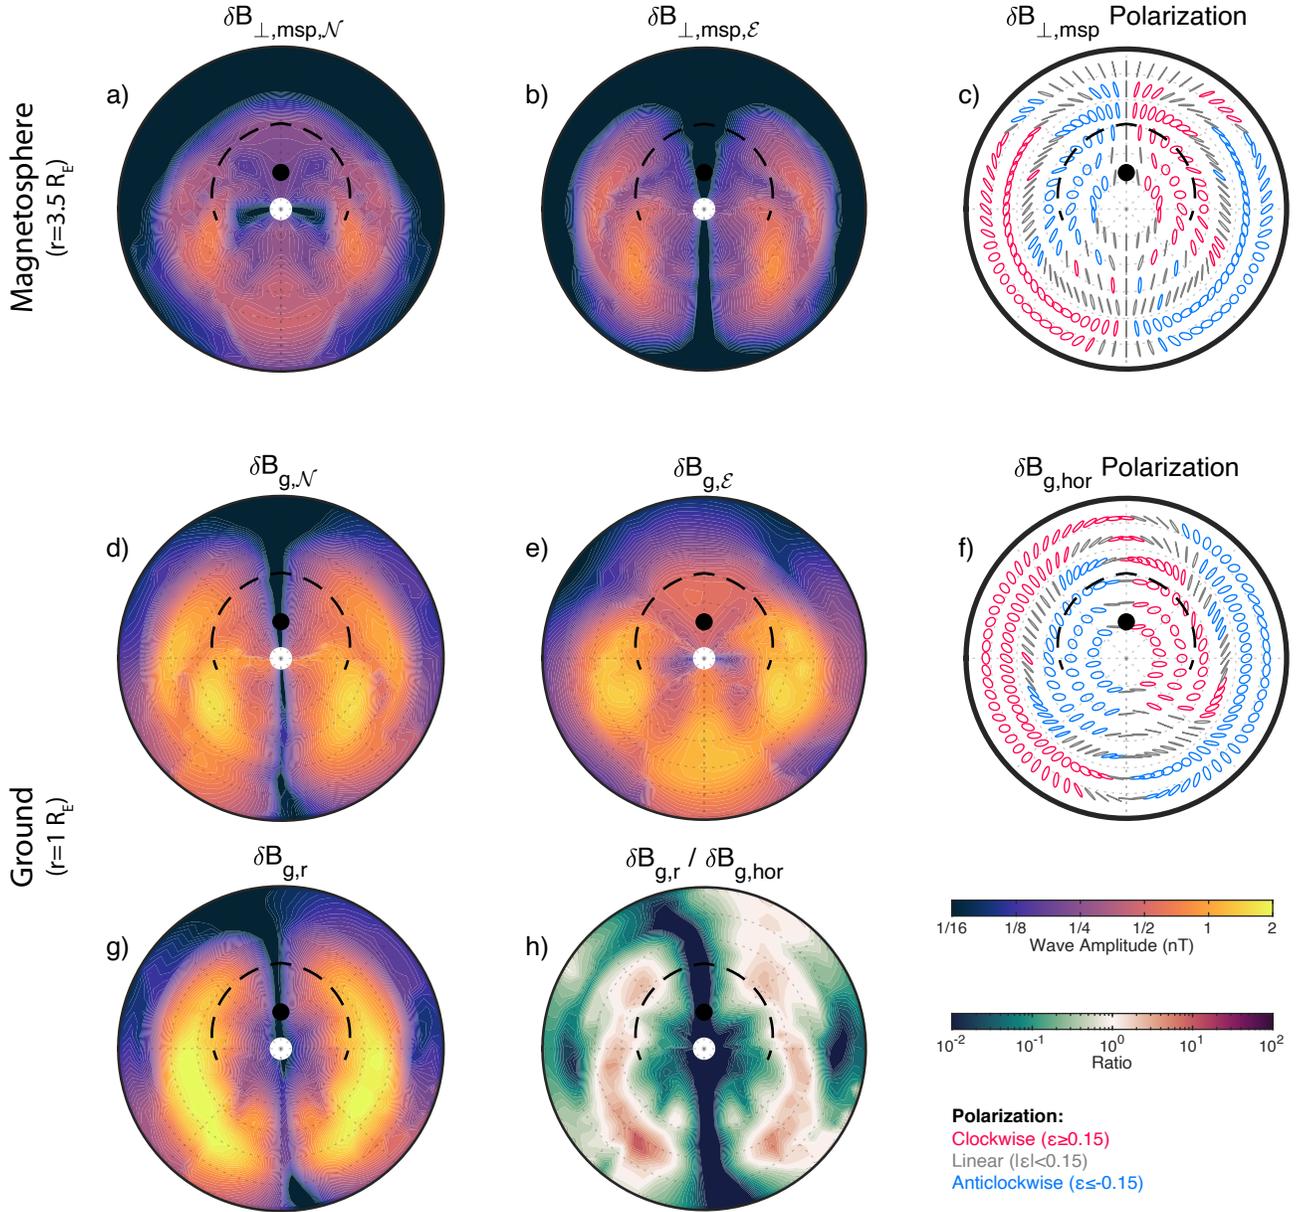

Figure 5: Comparison of magnetic perturbations (a–c) near the magnetosphere–ionosphere interface, and (d–h) on the ground. Fourier amplitudes (a,b,d,e,g) and polariation ellipses (c,f) are displayed. Finally, the ratio of vertical to horizontal ground perturbations is shown (g). Formats are similar to Figure 3e–g.
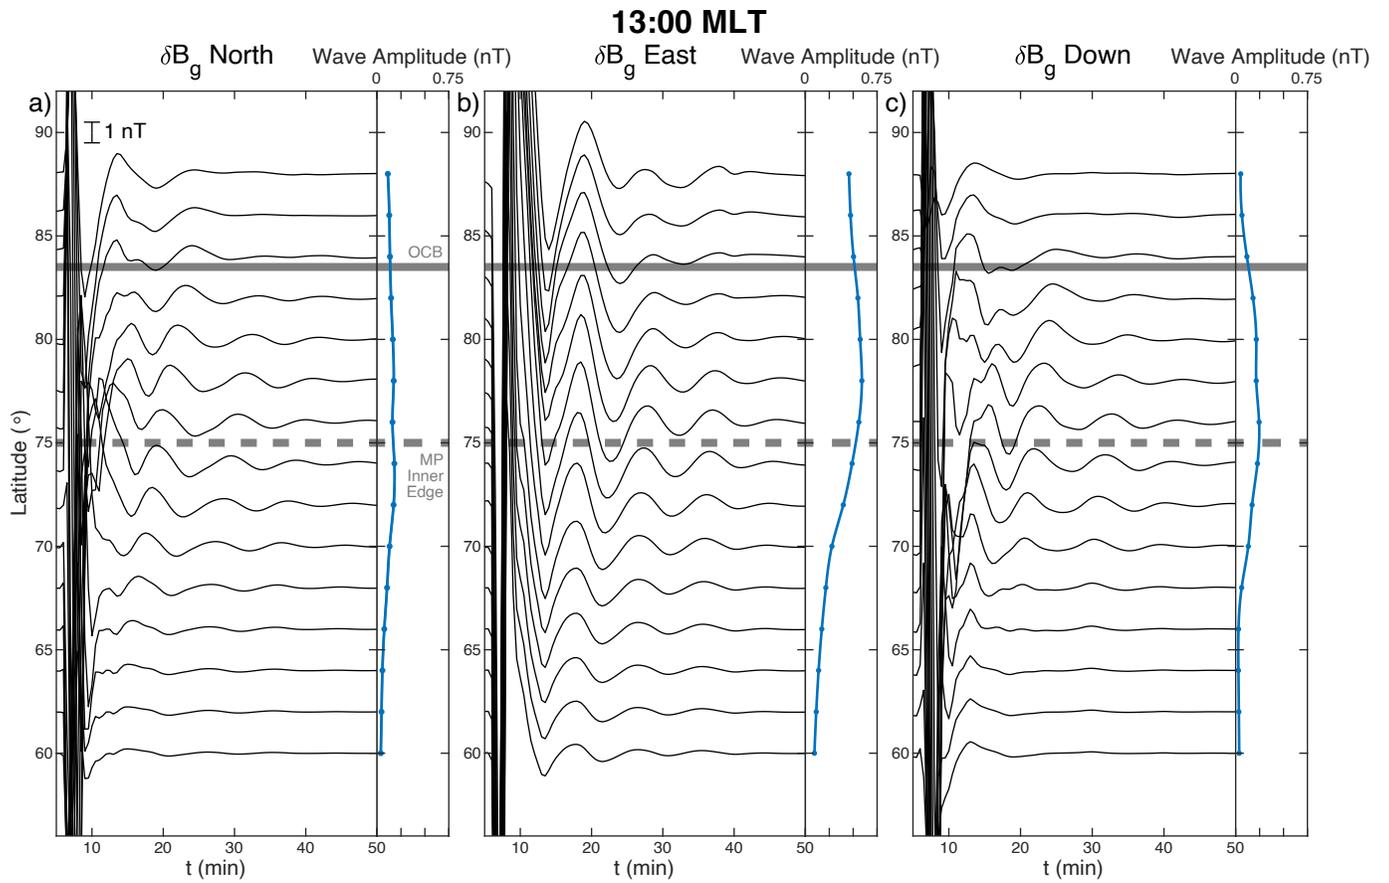

Figure 6: Examples of potential latitudinal ground magnetometer chain observations. Magnetic field perturbations in the (a) North-South, (b) East-West, and (c) vertical components are shown as stacked time-series (black) as well as Fourier amplitudes (blue). Grey lines depict projections of the open-closed boundary (solid) and magnetopause inner edge (dashed).

Appendix A Coefficient of Determination

The Coefficient of Determination, R^2, is the proportion of the variance in a dependent variable that is predictable from an independent variable, often used in statistical models to quantify how well outcomes are replicated. In the case that the variables are complex vector time-series, this is given by

$$R^2 = 1 - \frac{\int dt\,(\mathbf{y} - \mathbf{f}) \cdot (\mathbf{y} - \mathbf{f})^*}{\int dt\,\mathbf{y} \cdot \mathbf{y}^*} \tag{A1}$$

where $\mathbf{y}$ is the dependent variable and $\mathbf{f}$ is its predicted/modelled value. It follows from Parseval's theorem that for oscillatory signals R^2 can also be determined from the complex Fourier amplitudes (denoted by tildes here)

$$R^2 = 1 - \frac{\int df\,\left(\tilde{\mathbf{y}} \cdot \tilde{\mathbf{y}}^* - \tilde{\mathbf{y}} \cdot \tilde{\mathbf{f}}^* - \tilde{\mathbf{f}} \cdot \tilde{\mathbf{y}}^* + \tilde{\mathbf{f}} \cdot \tilde{\mathbf{f}}^*\right)}{\int df\,\tilde{\mathbf{y}} \cdot \tilde{\mathbf{y}}^*} \tag{A2}$$

R^2 can be interpreted as the fraction of explained variance, with $R^2 = 1$ corresponding to perfect prediction. Negative values are possible when the predictor performs worse than one which always predicts the mean value. In this paper we use R^2 to indicate what proportion of the total ground magnetic field perturbations are determined by contributions from different current systems. This has the benefits over simply comparing the root-mean-squared magnitudes of contributions (e.g. Rastätter et al., 2014) since the vector directions are also included.

Appendix B Rotation Angle

The signed right-handed rotation angle from a vector $\mathbf{b}$ to $\mathbf{a}$ about some direction $\hat{\mathbf{z}}$ may be expressed as

$$\Delta\theta = \mathrm{atan2}\left([\mathbf{b} \times \mathbf{a}] \cdot \hat{\mathbf{z}},\, \mathbf{b} \cdot \mathbf{a}\right) \tag{B1}$$

In the case of oscillatory vectors, the time-average (angular brackets) of $\Delta\theta$ can be arrived at by using the following properties of complex Fourier amplitudes

$$\begin{aligned}
\langle \mathbf{b} \times \mathbf{a}\rangle &= \tfrac{1}{2}\mathrm{Re}\left\{\tilde{\mathbf{b}} \times \tilde{\mathbf{a}}^*\right\} \\
\langle \mathbf{b} \cdot \mathbf{a}\rangle &= \tfrac{1}{2}\mathrm{Re}\left\{\tilde{\mathbf{b}} \cdot \tilde{\mathbf{a}}^*\right\}
\end{aligned} \tag{B2}$$

and hence

$$\langle \Delta\theta \rangle = \mathrm{atan2}\left(\mathrm{Re}\left\{\tilde{\mathbf{b}} \times \tilde{\mathbf{a}}^*\right\} \cdot \hat{\mathbf{z}},\, \mathrm{Re}\left\{\tilde{\mathbf{b}} \cdot \tilde{\mathbf{a}}^*\right\}\right) \tag{B3}$$

923   In this paper, we use this to calculate the rotation of the horizontal magnetic field com-

924   ponents from above the ionosphere to below it. Thus the direction $\hat{\mathbf{z}}$ is taken as the ver-

925   tical/radial.
