## Key Points:

- Dynamics of riverine  $\text{NO}_3^-$  are controlled by vertical concentration heterogeneity resulting from subsurface reactivity
- Diffuse P sources exert an unexpectedly strong control on the spatial variability of  $\text{PO}_4^{3-}$  export patterns in contrast to point sources
- Riparian wetlands as source areas control mean TOC concentrations, yet export dynamics are not well explained by catchment characteristics

## 22 **Abstract**

23 Elevated nutrient inputs and reduced riverine concentration variability challenge the health and  
24 functioning of aquatic ecosystems. To improve riverine water quality management, it is  
25 necessary to understand the underlying biogeochemical and physical processes and their  
26 interactions at catchment scale. We hypothesize that spatial heterogeneity of nutrient sources  
27 dominantly controls the variability of instream concentrations among different catchments.  
28 Therefore, we investigated controls of mean nitrate ( $\text{NO}_3^-$ ), phosphate ( $\text{PO}_4^{3-}$ ), and total organic  
29 carbon (TOC) concentrations and concentration-discharge (C-Q) relationships from observations  
30 in 787 German catchments covering a wide range of physiographic and anthropogenic settings.  
31 Using partial least square regressions and random forests we linked water quality metrics to  
32 catchment characteristics. We found archetypal C-Q patterns with enrichment dominating  $\text{NO}_3^-$   
33 and TOC, and dilution dominating  $\text{PO}_4^{3-}$  export. Across the catchments, we found a positive but  
34 heteroscedastic relation between mean  $\text{NO}_3^-$  concentrations and agricultural land use. We argue  
35 that denitrification, particularly pronounced in sedimentary aquifers, buffers high inputs and  
36 causes a decline in concentration with depth resulting in chemodynamic, strongly positive C-Q  
37 patterns. Consequently, chemodynamic  $\text{NO}_3^-$  enrichment patterns could indicate effective  
38 subsurface denitrification. Mean  $\text{PO}_4^{3-}$  concentrations were related to point sources though the  
39 low predictive power suggests effects of unaccounted processes. In contrast, diffuse inputs better  
40 explained the spatial differences in  $\text{PO}_4^{3-}$  C-Q patterns. TOC levels were positively linked to the  
41 abundance of riparian wetlands as well as negatively to  $\text{NO}_3^-$  concentrations suggesting  
42 interacting processes. This study shows that vertical concentration heterogeneity mainly drives  
43 nutrient export dynamics, partially modified by interactions with other controls.

## 44 **Plain Language Summary**

45 The major nutrients phosphorus, nitrogen and carbon, are main components of plants and all  
46 living organisms. Humans are altering the nutrient cycles especially to improve agricultural  
47 productivity. However, excess nutrients in surface waters have harmed many aquatic ecosystems  
48 through toxic algal blooms and loss of biodiversity. Low concentrations with a natural variability  
49 of concentrations are similarly important to those ecosystems but human interference with  
50 natural drivers is not yet fully understood. To unravel if natural or human controls dominate, we  
51 investigate nutrient concentrations and their variability over a wide range of different landscapes  
52 and conditions. The human impact is clearly visible for mean nitrate concentrations, while the  
53 subsurface properties seem to control the variability of riverine nitrate allowing to predict  
54 subsurface conditions from riverine nitrate dynamics. In the past phosphate inputs had usually  
55 been linked to wastewater, yet, we found the control of agricultural activities on concentration  
56 dynamics to be unexpectedly high. Organic carbon was associated mainly with natural sources  
57 related to riparian wetlands where interactions with other nutrients are possible. This  
58 understanding of dominant controls is important for adapting management strategies to ensure  
59 healthy aquatic ecosystems.

## 60 **1 Introduction**

61 Human activities put aquatic ecosystems under pressure by elevated nutrient inputs from  
62 fertilizer applications and wastewater sources. The health and functioning of stream ecosystems  
63 and eutrophication risk are strongly linked to levels and temporal variability of nutrient  
64 concentrations (Hunsaker & Johnson, 2017; Pascal et al., 2013; Withers & Jarvie, 2008).  
65 Moreover, the dynamics of nutrient concentrations in concert with discharge control nutrient

66 loads exported from catchments to downstream water bodies and finally to the oceans causing  
67 eutrophication in many estuaries of the world (Bricker et al., 1999; EEA, 2018). Adverse effects  
68 of eutrophication are hypoxia, toxic algal blooms, fish kills, loss of biodiversity, limitations for  
69 drinking water, and structural and functional changes in ecosystems (Le Moal et al., 2019; Smith,  
70 2003; Smith et al., 1999). Therefore, eutrophication is one of the major global water quality  
71 concerns and understanding mobilization and retention processes of nutrients becomes crucial  
72 for a sustainable nutrient management.

73 Several national and European regulations have been adopted to reduce nutrient-related  
74 water quality problems. Initially, the focus was on reducing nutrient inputs related to point  
75 sources (BGBl.1, 1980; Copeland, 2016; ECC, 1991) but later regulations additionally addressed  
76 nonpoint-source pollution (Copeland, 2016; EEC, 1991, 2000). In the European Union, the  
77 Water Framework Directive (WFD, EEC, 2000) set water quality aims and guidelines including  
78 the reduction of diffuse pollution, e.g. from agricultural fields, and demanding a river basin and  
79 ecology-oriented perspective for water quality management. Still, many surface water bodies  
80 worldwide lack a good ecological status, with diffuse sources from agriculture being one of the  
81 main pressures (Damania et al., 2019; EEA, 2018; EPA, 2017).

82 Measures to improve the water quality are usually implemented and evaluated at  
83 catchment scale (e.g., Bouraoui & Grizzetti, 2011). Yet, catchments are complex and  
84 heterogeneous systems within which multiple biogeochemical and hydrological processes  
85 interact at different spatial and temporal scales (Bouwman et al., 2013; Clark et al., 2010),  
86 integrating into water quantity and quality responses observed at the catchment outlet (Bouraoui  
87 & Grizzetti, 2011). A considerable amount of nutrients can be retained or degraded in different  
88 compartments, such as soils, groundwater, riparian zones, and streams, altogether considered as  
89 successive filters, reducing loads transported downstream (Bouwman et al., 2013). The  
90 importance of processes on transported loads generally depends on the interplay between  
91 transport and reaction time scales (Musolff, Fleckenstein, et al., 2017; Oldham et al., 2013).  
92 Those may vary spatio-temporally creating “hot spots” and “hot moments” (McClain et al.,  
93 2003). Hierarchies and interactions among processes and different scales as well as differences  
94 among catchments are still not properly understood and upscaling of small-scale processes to the  
95 catchment scale remains a challenging task (e.g., Bol et al., 2018; Pinay et al., 2015).

96 Data-driven inductive analyses allow characterizing the observed integrated catchment  
97 responses and thereby inferring dominant processes, which operate within a catchment. By  
98 revealing linkages, top-down analyses provide approaches that allow for interpretation of drivers  
99 but cannot prove their causality, which can be further strengthened in combination with  
100 modeling and experimental work. Mean concentrations (C) indicate the general levels of nutrient  
101 stress, while concentration-discharge (C-Q) relationships classify solute export dynamics in  
102 terms of export regimes and patterns (Musolff et al., 2015), which reflects the underlying  
103 biogeochemical and hydrological processes. A chemostatic regime is defined as relatively low C  
104 variability compared to high discharge (Q) variability, while a chemodynamic regime defines a  
105 relatively high C to Q variability. Export patterns characterize the direction and strength of  
106 influence of Q on C. Enrichment or accretion patterns describe increasing C with increasing Q,  
107 while dilution describes decreasing C with increasing Q. Enrichment patterns emerge if  
108 additional sources get accessed with additional discharge generating areas (transport-limitation).  
109 On the other hand, dilution patterns prevail in supply-limited systems. When comparing C-Q  
110 relationships among different solutes and catchments, generalities and key controls of solute

111 export can be identified (Minaudo et al., 2019; Musolff et al., 2015; Zarnetske et al., 2018).  
112 Therefore, C-Q relationships have been widely applied to determine water quality and quantity  
113 functioning at different temporal (i.e. event, inter- and intra-annual, e.g. Dupas et al. (2016);  
114 Minaudo et al. (2019); Rose et al. (2018); Westphal et al. (2019)) and spatial scales (from  
115 hillslope and headwaters, e.g. Bishop et al. (2004); Herndon et al. (2015); Hunsaker and Johnson  
116 (2017), to numerous, large and nested catchments, e.g. Basu et al. (2010); Evans et al. (2014);  
117 Moatar et al. (2020)). Prevailing C-Q patterns depend on element properties (Minaudo et al.,  
118 2019; Moatar et al., 2017) while the encountered variability in export dynamics can partly be  
119 explained by catchment characteristics (e.g., Musolff et al., 2015). Variable end-member mixing  
120 and other time-variant controls of C can cause scatter in C-Q relationships (e.g., Burns et al.,  
121 2019), related to e.g. event hysteresis (e.g., Benettin et al., 2017; Tunaley et al., 2017), variable  
122 antecedent and seasonal conditions (e.g., Werner et al., 2019; Winterdahl et al., 2011) or changes  
123 in sources (e.g., Westphal et al., 2019).

124 To understand riverine nutrient export dynamics we require process understanding of the  
125 major elements of catchment scale transport – input, mobilization and retention. Nitrogen (N),  
126 phosphorus (P) and carbon are major macro nutrients but anthropogenic activities have altered  
127 their cycles and occurrence in water, including excess N and P in surface waters. Mean nitrate  
128 ( $\text{NO}_3$ ) concentrations increase with higher shares of agricultural land (e.g., Evans et al., 2014;  
129 Hansen et al., 2018; Minaudo et al., 2019; Musolff et al., 2015), while phosphate ( $\text{PO}_4$ )  
130 concentrations have been mainly related to point sources (Minaudo et al., 2019; Westphal et al.,  
131 2019). With significant point source reductions, though, diffuse P emissions from agricultural  
132 soils become increasingly relevant (e.g., Bol et al., 2018; Le Moal et al., 2019; Schoumans et al.,  
133 2014). Elevated inputs could be counteracted by removal, e.g. by denitrification under anoxic  
134 conditions and availability of electron donors observed in wetlands (e.g., Hansen et al., 2018)  
135 and riparian zones (e.g., Lutz et al., 2020; Pinay et al., 2015; Rivett et al., 2008; Sabater et al.,  
136 2003), though local heterogeneities complicate the upscaling of removal capacities from site to  
137 catchment scale (Pinay et al., 2015). Moreover, denitrification can be small compared to  
138 temporary N retention related to assimilation in soil or stream compartments (Lutz et al., 2020).  
139 P retention and delivery to streams are closely linked to sorption in soils influenced by abiotic  
140 factors such as pH and redox conditions (Withers & Jarvie, 2008). During rewetting after warm  
141 periods or under anoxic conditions causing Fe hydroxide dissolution, riparian wetlands can act as  
142 a P source instead of as a sink for agricultural P (Dupas, Gruau, et al., 2015; Gu et al., 2017). For  
143 organic carbon, sources are linked to zones of organic matter accumulation, where biomass  
144 production exceeds removal via complete decomposition, e.g. in wetlands and peatlands (e.g.,  
145 Clark et al., 2010). Therefore, riparian zones are important source areas (e.g., Clark et al., 2010;  
146 Kalbitz et al., 2000; Laudon et al., 2011; Musolff et al., 2018), where dissolved organic carbon  
147 (DOC) can also be consumed serving as electron donor in redox reactions e.g. denitrification.  
148 Riparian zones are usually hydrologically connected to the stream whereas more distant DOC  
149 source areas might not intersect discharge generating zones (Bishop et al., 2004). Riparian zones  
150 are thus potential hot spots of biogeochemical processes, including denitrification, DOC  
151 production and both P trapping and release, which are all linked to redox conditions and thus  
152 water table dynamics. After the delivery to the stream, instream processes, like redox reactions  
153 and uptake, can further remove, retain, transform or remobilize the nutrients before reaching the  
154 catchment outlet (Battin et al., 2008; Gomez-Velez et al., 2015).

155 Next to the sources, mobilization and transport mechanisms and reactivity together  
156 determine when and how dynamically constituents are exported. Generally, the interplay

157 between the solute source areas and hydrological connectivity has been found to control solute  
158 export dynamics (e.g., Herndon et al., 2015; Musolff, Fleckenstein, et al., 2017; Seibert et al.,  
159 2009; Thompson et al., 2011; Tunaley et al., 2017). If solute source areas are uniformly  
160 distributed in a catchment, a chemostatic regime establishes, typical for geogenic solutes  
161 (Thompson et al., 2011). Previous studies have found evidence that  $\text{NO}_3$  often exhibits a  
162 chemostatic export regime in managed agricultural catchments (e.g., Basu et al., 2010; Basu et  
163 al., 2011; Dupas et al., 2016). This chemostatic regime is attributed to the build-up legacy of  
164 high N inputs in the past causing spatial homogenization of sources (Basu et al., 2010;  
165 Thompson et al., 2011), suggesting a significant anthropogenic impact on  $\text{NO}_3$  export dynamics.  
166 Similarly, excess P inputs have led to P-legacies in soils and sediments (Jarvie et al., 2013;  
167 Schoumans et al., 2015; Sharpley et al., 2013). Legacy effects may hamper mitigation measures  
168 to reduce exported nutrient loads by dampening concentration responses and creating time lags  
169 (e.g., Bouraoui & Grizzetti, 2011; Howden et al., 2010; Meals et al., 2010; Van Meter & Basu,  
170 2015; Wang et al., 2016). In contrast, chemodynamic regimes are related to heterogeneously  
171 distributed source areas and variable discharge generating zones (e.g., Musolff, Fleckenstein, et  
172 al., 2017; Zhi et al., 2019). Source heterogeneity can be linked, for example, to distinct  
173 production zones and resulting vertical soil distribution profiles (Seibert et al., 2009) and  
174 landscape patterns (Dupas, Gascuel-Oudou, et al., 2015; Herndon et al., 2015) as shown for DOC  
175 and to heterogeneous land use patterns and connected inputs such as fertilizers (Musolff,  
176 Fleckenstein, et al., 2017). Chemodynamic exports can also result from reactions along flow  
177 paths affecting longer travel times more than shorter ones leading to enrichment patterns for  
178 removal (Musolff, Fleckenstein, et al., 2017) and dilution for production or accumulation  
179 processes (Ameli et al., 2017; Musolff, Fleckenstein, et al., 2017). Moreover, transient processes  
180 can cause temporal variations in source zones, e.g. long-term input changes from fertilizer  
181 applications (Ehrhardt et al., 2019) or temporally variable production and accumulation in drying  
182 and wetting cycles (Gu et al., 2017). In summary, chemodynamic regimes signal variable  
183 combinations of discharge generating zones with different solute source strengths, travel times  
184 and reactivity along the flow paths within a catchment.

185 The anthropogenic impact on nutrient cycles and their consequence for concentration  
186 levels in streams (e.g., Gruber & Galloway, 2008; Hansen et al., 2018; Howden et al., 2010) as  
187 well as for nutrient export regimes has been discussed in several studies. However, only few  
188 studies to date have used a large number of catchments and various solutes to draw more general  
189 conclusions which requires a large sample size (Gupta et al., 2014). Thus it remains uncertain  
190 how general and wide-spread the anthropogenic impact and resulting homogeneity or  
191 heterogeneity of sources is over a wide range of landscapes compared to natural controls,  
192 heterogeneity and reactivity, and how persistent the effect of anthropogenic-induced chemostatic  
193 export is (Ehrhardt et al., 2019; Van Meter & Basu, 2017). Therefore, we seek to understand (1)  
194 what drives nutrient concentration levels and dynamics across a large variety of catchments and  
195 (2) how anthropogenic impacts such as nutrient inputs interact with natural factors such as the  
196 hydroclimate, topography, and subsurface conditions. Our exploratory analysis is guided by the  
197 hypothesis that spatial heterogeneity of diffuse sources is the major control of the variability of  
198 riverine nutrient concentrations.

199 To this end, we use mean C and C-Q relationships of  $\text{NO}_3\text{-N}$ ,  $\text{PO}_4\text{-P}$  and total organic  
200 carbon (TOC) to investigate and classify riverine nutrient dynamics in 787 independent  
201 catchments in Germany covering a wide range of ecoregions and large gradients in physical and  
202 hydroclimatic properties. We assess the predictive power of anthropogenic and natural catchment

203 properties to infer dominant controls and hypothesize about underlying processes by linking the  
 204 descriptors to C-Q export metrics with partial least square regression (PLSR) and random forest  
 205 (RF) models. Potential predictors include topography, land cover, geology, hydroclimate, diffuse  
 206 and point sources and proxies for spatial source heterogeneity. This approach allows addressing  
 207 the generality of patterns, testing existing hypothesis on a large number of catchments and  
 208 discussing hierarchies of natural and anthropogenic controls of export metrics. Knowledge on  
 209 drivers of nutrient export potentially serves to improve nutrient export models at catchment scale  
 210 and develop management tools.

## 211 **2 Materials and Methods**

### 212 2.1. Water Quality and Quantity Data Set

213 Water quality data from river stations across Germany were gathered from the German  
 214 Federal state environmental authorities (Musolff, 2020; Musolff et al., 2020). The authorities  
 215 regularly monitor the surface water quality in the context of the WFD (EEC, 2000) taking grab  
 216 samples with a biweekly to seasonal frequency. Here, we focussed on the major nutrients:  
 217 nitrate-N concentrations as the dominant form of dissolved N ( $\text{NO}_3^-$ -N), the biologically  
 218 available dissolved orthophosphate-phosphorus ( $\text{PO}_4^{3-}$ -P) and total organic carbon concentrations  
 219 (TOC). For carbon, we used TOC instead of DOC samples because of better data availability and  
 220 a strong correlation with a regression slope of about 0.87 between mean DOC and TOC  
 221 concentrations (see Figure S1), and DOC representing about 81.3 ( $\pm$  7.9) % of TOC on average.  
 222 For water quantity, daily mean discharge time series at the water quality locations were partly  
 223 provided together with the quality data (Musolff, 2020; Musolff et al., 2020).

224 Out of the initial pool of 6000 sites, water quality time series were selected based on the  
 225 following criteria concerning the quality and availability of concentration data and spatial data:

226 1) Data availability of at least three years in target period from 2000 to 2015. This time  
 227 period excludes major changes of the 1990s when major improvements of wastewater treatment  
 228 were put into place (Westphal et al., 2019).

229 2) Minimum of 70 concentration samples after outlier removal. As the large number of  
 230 sites demanded a cost-effective method, only extreme outliers likely to be typographical errors  
 231 were removed (following Oelsner et al., 2017). We defined outliers as concentrations  $>$  mean C  
 232 + 4\*standard deviation in logarithmic space (confidence level  $>$  99.99 % assuming lognormal  
 233 distribution of concentrations) and as  $\text{PO}_4$ -P concentrations  $>$  100 mg  $\text{l}^{-1}$ , and TOC  
 234 concentrations  $>$  1000 mg  $\text{l}^{-1}$  in terms of absolute values.

235 3) Seasonal coverage of the concentration data, i.e. the samples within any of the four  
 236 seasons (starting in October, November and December) constitutes at least 10% of the samples  
 237 on average. This includes stations with data systematically missing in one month.

238 4) Left censored data of the concentration time series (values below the detection limit)  
 239 must be less than 50% of the samples.

240 5) Catchment area must be delineable from topography, i.e. we excluded stations with  
 241 apparent, major deviations between location of real river network and topography-based basin  
 242 area. The catchments were delineated based on flow accumulation derived from a digital  
 243 elevation model (DEM, EEA, 2013) of 25 m resolution resampled to 100 m and the river  
 244 network from the CCM River and Catchment Database (version 2.1 (CCM2)(De Jager & Vogt,

245 2007)) with some manual adaptations of river segments which drastically improve the match  
246 between catchments and the real river network.

247 6) Independence of catchments, which was defined as nested catchments sharing less  
248 than 20% of their catchment area with any upstream station.

249 7) Station must not be directly located at the outlet of a reservoir or lake, because the  
250 water quality is expected to be mainly a result of lake dynamics, thus masking the catchment  
251 processes.

252 8) Data availability of catchment characteristics. This leads to the criterion that a  
253 minimum of 70% of the catchment area must fall within the borders of Germany, as some of the  
254 geodata were limited to Germany, such as N-surplus and point sources (see Section 2.3).

255 Applying the above criteria resulted in a set of 787 catchments with 759 NO<sub>3</sub>-N, 695  
256 PO<sub>4</sub>-P, and 722 TOC time series. Out of those catchments, at 278 sites observed daily discharge  
257 data were available. Altogether, the analysed data base consists of a total of 110,603  
258 concentration samples for combinations of dates and locations with an average between 135  
259 (TOC) and 142 (NO<sub>3</sub>-N) samples per site (from 2000 to 2015).

## 260 2.2. Metrics of Water Quality Dynamics

261 We used mean concentrations and metrics of the C-Q relationships to characterize the  
262 nutrient concentration levels and dynamics in the different catchments. Before calculating basic  
263 statistics at each station, i.e. mean concentrations and the standard deviation, we replaced the  
264 concentration values falling below the detection limit (left censored data) with half of the  
265 detection limit (see e.g., Hunsaker & Johnson, 2017; Underwood et al., 2017). Slope  $b$  of the  
266 linear relation between logarithmic concentration ( $C$ ) and discharge ( $Q$ ) following:  $\log(C) =$   
267  $\log(a) + b \cdot \log(Q)$  (equals power law relationship  $C = a \cdot Q^b$ ) (Godsey et al., 2009) was calculated  
268 for all stations. Slope  $b$  characterizes the export pattern of a solute or particulates:  $b > 0$  indicates  
269 an enrichment or accretion pattern,  $b < 0$  a dilution pattern, while  $b \approx 0$  describes a non-  
270 significant, neutral C-Q pattern (Musolff, Fleckenstein, et al., 2017). Note that we consider a  
271 distinction between the export patterns based on the significant difference of the slope  $b$  from  
272 zero (t-test, 95% significance level) more appropriate than fixed, predefined range of slope  $b$  that  
273 have also been used (Herndon et al., 2015; Zimmer et al., 2019). Further note that slope  $b$  was  
274 determined up to censoring degrees of 20% by excluding the censored values from the regression  
275 assuming that no major part of the C-Q relationship will be missed by the data.

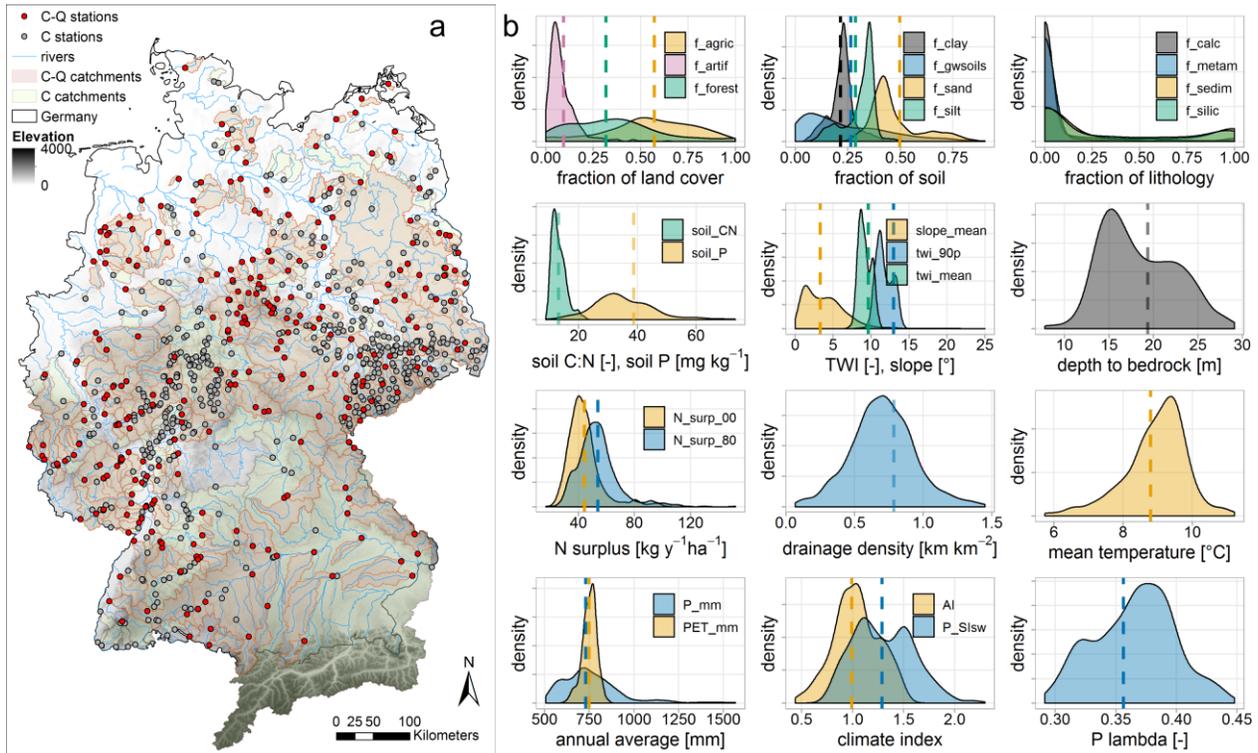

276 Additionally, we used the ratio of the coefficients of variation of concentration and  
277 discharge  $CV_C/CV_Q$  to characterize export regimes (Thompson et al., 2011). If  $CV_C/CV_Q$  is  
278 small ( $< 0.5$ ), the export regime is chemostatic (i.e.  $C$  variations are small compared to variations  
279 in  $Q$ ), while high values  $CV_C/CV_Q$  indicate a chemodynamic (i.e.  $C$  variations are large  
280 compared to variations in  $Q$ ) export regime (Musolff et al., 2015). The combination of both  
281 statistics: slope  $b$  and  $CV_C/CV_Q$  allows distinguishing combinations of chemostatic and  
282 chemodynamic regimes within the different export patterns. This distinction is especially  
283 important for non-significant C-Q relationships, which can still demonstrate a chemodynamic  
284 export with  $C$  variability related to other factors than  $Q$ .

285 Based on the combination of export patterns and regimes, the studied catchments were  
286 categorized into six distinct export classes (see Supplementary Figure S2). Differences in mean  
287 concentrations between the export patterns and regimes were tested for significance ( $\alpha=0.05$ )

288 using a Kruskal-Wallis rank sum test. In case of significant differences between the C-Q  
 289 patterns, the Wilcoxon rank sum test was used for pairwise comparisons to identify which  
 290 patterns differ.

### 291 2.3. Catchment Characteristics

292 The 278 C-Q catchments with available discharge data cover an area of 43.7% of  
 293 Germany, while the 787 C catchments cover 65.6%. Catchment sizes vary from 1.9 to  
 294 77099.2 km<sup>2</sup> (4.4 to 23162.7 km<sup>2</sup> for C-Q catchments), with 50% of the catchments < 97.1 km<sup>2</sup>  
 295 (< 235.6 km<sup>2</sup>) and 95% < 1257.4 km<sup>2</sup> (< 2540.0 km<sup>2</sup>). The catchments intersect all 10  
 296 hydrogeological regions in Germany (BGR & SGD, 2015) and span a wide range of  
 297 topographical, hydroclimatic, lithological and soil properties with varying anthropogenic  
 298 presence. A summary of calculated characteristics is given in Table 1 and represented  
 299 distributions of selected catchment characteristics, matching mean conditions in Germany,  
 300 are shown in Figure 1. The selection of characteristics to consider was inspired by several previous  
 301 studies (e.g., Botter et al., 2013; Dupas, Delmas, et al., 2015; Moatar et al., 2017; Musolff et al.,  
 302 2018; Musolff et al., 2015; Onderka et al., 2012) and limited by availability over the large scale.

303  
 304 **Figure 1.** The study area with stations of concentration (C) and additional discharge (C-Q) data  
 305 and corresponding catchments overlaying elevation (a) and distributions of selected catchment  
 306 characteristics represented by the C catchments (b). TWI – topographic wetness index, P<sub>mm</sub> –  
 307 precipitation, PET<sub>mm</sub> – potential evapotranspiration, AI – aridity index. For further  
 308 abbreviations and explanations of the parameters refer to Table 1. Vertical dashed lines mark  
 309 corresponding average values for Germany.

310 **Table 1.** Catchment Descriptors Used in the Analysis, Associated Methods and Data Sources

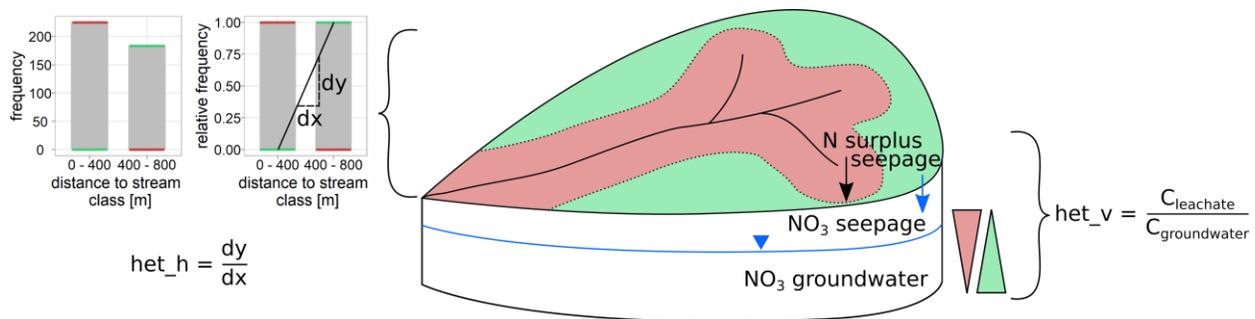

Category	Variable	Unit	Description and method	Data source
----------	----------	------	------------------------	-------------

Topography	area	km <sup>2</sup>	Catchment area	
	dem_mean	mamsl	Mean elevation of catchment, from DEM rescaled from 25 to 100 m resolution using average	EEA (2013)
	slope_mean	°	Mean topographic slope of catchment, from DEM	EEA (2013)
	twi_mean	-	Mean topographic wetness index (TWI, Beven & Kirkby, 1979)	EEA (2013)
	twi_90p	-	90 <sup>th</sup> percentile of the TWI as a proxy for riparian wetlands (following Musolff et al., 2018)	EEA (2013)
	drain_dens	km <sup>-1</sup>	Average drainage density of the catchment. Gridded drainage density is provided as the length of surface waters (rivers and lakes) per area from a 75km <sup>2</sup> circular area around each cell center.	BMU (2000)
Land cover	f_urban	-	Fraction of artificial land cover	CLC (2016)
	f_agric	-	Fraction of agricultural land cover	CLC (2016)
	f_forest	-	Fraction of forested land cover	CLC (2016)
	f_wetland	-	Fraction of wetland cover	CLC (2016)
	f_water	-	Fraction of surface water cover	CLC (2016)
	p_dens	persons km <sup>2</sup>	Mean population density	<i>CIESIN (2017)</i>
Nutrient sources	N_surp_00	kg N ha <sup>-1</sup> y <sup>-1</sup>	Mean nitrogen surplus per catchment during sampling period (2000-2015) including N surplus on agricultural land and atmospheric deposition on non-agricultural areas	Bach et al. (2016); Häußermann et al. (2019)
	N_surp_80	kg N ha <sup>-1</sup> y <sup>-1</sup>	Mean N surplus per catchment before and during sampling period (1980-2015) to consider historic (legacy) inputs	Bach et al. (2016); Häußermann et al. (2019)
	N_WW	kg N ha <sup>-1</sup> y <sup>-1</sup>	Sum of N input from point sources including waste water treatment plants (WWTP) > 2000 person equivalents from the database of the European Environment Agency covering areas beyond Germany and data collected from 13 Federal German States covering smaller WWTP within Germany	Büttner (2020a, 2020b)
	P_WW	kg P ha <sup>-1</sup> y <sup>-1</sup>	Sum of P input from WWTP analogous to N_WW	Büttner (2020a, 2020b)
	het_h	-	Slope of relative frequency of source areas in classes of flow distances to stream as a proxy for horizontal source heterogeneity (see in text Section 2.3)	Source areas based on Pflugmacher et al. (2018)
	sdist_mean	m	Mean lateral flow distance of source areas to stream (see in text Section 2.3)	Source areas based on Pflugmacher et al. (2018)
	het_v	-	Mean ratio between potential seepage and groundwater NO <sub>3</sub> -N concentrations as proxy for vertical concentration heterogeneity (see in text Section 2.3)	Knoll et al. (2020)
Lithology and soils	f_calc	-	Fraction of calcareous rocks	BGR & UNESCO (eds.) (2014)
	f_calc_sed	-	Fraction of calcareous rocks and sediments	BGR & UNESCO (eds.) (2014)
	f_magma	-	Fraction of magmatic rocks	BGR & UNESCO (eds.) (2014)
	f_metam	-	Fraction of metamorphic rocks	BGR & UNESCO (eds.) (2014)
	f_sedim	-	Fraction of sedimentary aquifer	BGR & UNESCO (eds.) (2014)
	f_silic	-	Fraction of siliciclastic rocks	BGR & UNESCO (eds.) (2014)
	f_sili_sed	-	Fraction of siliciclastic rocks and sediments	BGR & UNESCO (eds.) (2014)
	dtb	cm	Median depth to bedrock in the catchment	Shangguan et al. (2017)
	f_gwsoils	-	Fraction of water-impacted soils in the catchment (from soil map 1:250,000), including stagnosols, semi-terrestrial, semi-subhydric, subhydric and moor soils	BGR (2018)
	f_sand	-	Mean fraction of sand in soil horizons of the top 100 cm	FAO/IASA/ISRIC/ISSC AS/JRC (2012)
	f_silt	-	Mean fraction of silt in soil horizons of the top 100 cm	
	f_clay	-	Mean fraction of clay in soil horizons of the top 100 cm	
	water_root	mm	Mean available water content in the root zone from pedo-	Livneh et al. (2015); Samaniego et al. (2010);

			transfer functions	Zink et al. (2017)
theta_S	-		Mean porosity in catchment from pedo-transfer functions	Livneh et al. (2015); Samaniego et al. (2010); Zink et al. (2017)
soil_N	g kg <sup>-1</sup>		Mean top soil N in catchment	Ballabio et al. (2019)
soil_P	mg kg <sup>-1</sup>		Mean top soil P in catchment	Ballabio et al. (2019)
soil_CN	-		Mean top soil C/N ratio in catchment	Ballabio et al. (2019)
Climate	P_mm	mm	Mean annual precipitation (period 1986-2015 used for all climatic variables)	Cornes et al. (2018)
	P_Slsw	-	Seasonality of precipitation as the ratio between mean summer (Jun-Aug) and winter (Dec-Feb) precipitation	Cornes et al. (2018)
	P_lambda	-	Mean precipitation frequency $\lambda$ as used by Botter et al. (2013)	Cornes et al. (2018)
	PET_mm	mm	Mean potential evapotranspiration	Cornes et al. (2018)
	AI	-	Aridity index as $AI = PET\_mm / P\_mm$	Cornes et al. (2018)
	T_mean	°C	Mean annual temperature	Cornes et al. (2018)

311 Next to climatic characteristics available for all catchments, hydrological characteristics  
 312 were calculated for a smaller subset of catchments where daily discharge measurements were  
 313 available (n=186). The hydrological variables include mean discharge, specific discharge, runoff  
 314 coefficient, seasonal ratio, base flow index (BFI, WMO, 2008) and flashiness index based on  
 315 flow percentiles following Jordan et al. (2005). More details on the hydrological variables and  
 316 results are presented in the supporting information (Table S3 and S9-11).

317 To test our guiding hypothesis over a wide range of catchments, we parameterize source  
 318 heterogeneity from landscape characteristics. Inspired by Musolff, Fleckenstein, et al. (2017),  
 319 who found “structured heterogeneity” - defined as nonlinear correlation between source  
 320 concentration and travel time - dominantly shape C-Q relationships, we aim at connecting  
 321 discharge generating zones (implicitly related to travel times and water ages) with source  
 322 distributions. Thereby, we focus on parameterizing the prevailing structured heterogeneity in  
 323 each catchment as opposed to random variability and divide it into a horizontal and a vertical  
 324 parameterization component as shown in Figure 2.

325

326 **Figure 2.** Conceptualized parameterization for two different scenarios of horizontal source (red  
 327 area - sources close to stream, green area - sources relatively far from stream) and vertical  
 328 concentration heterogeneity (red – top-loaded concentration profile, green – bottom-loaded). If  
 329  $het\_h < 0$  it represents systems with sources relatively close to the stream,  $het\_h = 0$   
 330 homogeneously distributed,  $het\_h > 0$  relatively far from the stream. If  $het\_v < 1$  it represents a  
 331 bottom-loaded,  $het\_v = 1$  homogeneous and  $het\_v > 1$  a top-loaded concentration profile. For  
 332 horizontal source heterogeneity only two distance classes are shown for simplicity while more  
 333 classes are used for the real catchments.

334 For the horizontal source heterogeneity component of diffuse sources of NO<sub>3</sub>-N and PO<sub>4</sub>-  
335 P we assumed horizontal flow distances from the solute source to the stream network to link to  
336 flow paths and thus travel times. Source areas were defined as seasonal, perennial cropland and  
337 grassland land cover classes using a highly resolved land use map (Pflugmacher et al., 2018)  
338 representing diffuse anthropogenic nutrient sources. We computed horizontal flow distances  
339 along the topographic flow direction towards the stream using the ESRI ArcGIS (version 10.6).  
340 The stream grid was derived from the EU-wide EU-Hydro river network (EEA, 2016).  
341 According to the flow distance grid we resampled the land cover map with a 30 m resolution to  
342 100 m using the majority method. For each catchment, we determined the mean source area  
343 distance to stream (sdist\_mean) and the fraction of source area within classes of flow distances  
344 of 400 m each. Subsequently, we fitted a linear regression to the class values of the histogram  
345 weighed by the corresponding class frequencies within the catchment. If the slope of this  
346 regression is positive (het\_h > 0), source areas tend to be located further from the stream, while  
347 if it is negative (het\_h < 0), sources tend to be closer, and if het\_h = 0, sources are  
348 homogeneously distributed. Thus the slope is a proxy for horizontal source heterogeneity  
349 comparable to the parameter  $\gamma$  in Musolff, Fleckenstein, et al. (2017). As the EU-Hydro river  
350 network partly deviates from delineated catchments and contains different degrees of details, 78  
351 C and 38 C-Q catchments, especially small ones, contain implausible distance distributions.  
352 Therefore, catchments without intersection with any river segment or a maximum flow distance  
353 above 15 km were assigned as missing data. While these missing values lower the sample size,  
354 the related variables (het\_h and sdist\_mean) did not rank among the dominant predictors (as  
355 shown in the Results section) and therefore had been excluded from the main analysis results  
356 presented in Section 3.4. For the sake of completeness, analysis results corresponding to het\_h  
357 and sdist\_mean are presented in the supporting information (Table S4-5).

358 Similar to the horizontal source heterogeneity, we parameterized the vertical  
359 concentration heterogeneity as concentration gradients over depth. We again assume a link  
360 between flow paths over depth and travel times. For each catchment, we calculated the mean of  
361 the ratio between the potential seepage NO<sub>3</sub> concentrations and groundwater NO<sub>3</sub> concentrations  
362 as shown in Figure 2, resembling the parameter  $C_{ratio}$  used in Zhi et al. (2019). We used the  
363 groundwater NO<sub>3</sub> and potential seepage concentrations across Germany presented by Knoll et al.  
364 (2020). They estimated groundwater NO<sub>3</sub> concentrations with 1km resolution using a random  
365 forest model based on mean observed groundwater concentrations over the years 2009-2018 and  
366 spatial predictors, as previously introduced by Knoll et al. (2019). The potential seepage NO<sub>3</sub>  
367 concentrations (Knoll et al., 2020) were calculated as a ratio of N surplus (Bach et al., 2016;  
368 Häußermann et al., 2019) and the seepage rate (BGR, 2003). Due to data availability, vertical  
369 heterogeneity parameterization was calculated for NO<sub>3</sub> only but used as a descriptor for all  
370 nutrients.

#### 371 2.4. Linking Water Quality Metrics to Descriptors

372 We applied Partial Least Squares Regressions (PLSR, Wold et al., 2001) in combination  
373 with the Variable Influence of Projection (VIP, Wold et al., 2001) and Random Forests (RF,  
374 Breiman, 2001) to identify controls for differences in mean concentrations, export patterns and  
375 regimes of NO<sub>3</sub>-N, PO<sub>4</sub>-P and TOC among the studied catchments. Both models provide variable  
376 importance measures and can handle co-linearity between the descriptors as required in this  
377 study (see Figure S3 and Section 3.4) to link continuous variables, while PLSR is a linear and RF  
378 a non-linear method. Both models have been applied in water quality studies, e.g. PLSR for

379 investigating solute export and their predictors (Musolff et al., 2015; Onderka et al., 2012;  
 380 Wallin et al., 2015) and RF for estimating spatial distributions of groundwater NO<sub>3</sub>  
 381 concentrations (Knoll et al., 2019; Ouedraogo et al., 2019; Rodriguez-Galiano et al., 2014) and  
 382 artificial drainage systems (Møller et al., 2018). Here, we combine the two different approaches  
 383 as a model ensemble to improve the interpretability in terms of generalities in the identified  
 384 dominant predictors and thus face uncertainties related with data-driven analysis approaches, as  
 385 proposed e.g. by Schmidt et al. (2020).

386 One PLSR and one RF model per response variable was set up using the catchment  
 387 characteristics listed in Table 1 as descriptors for the complete set of catchments (excluding  
 388 *sdist\_mean* and *het\_h*). Besides, models including either *sdist\_mean* and *het\_h* or hydrological  
 389 descriptors were run for a small number of catchments due to missing values and presented in the  
 390 supporting information (Table S4-5). Nutrient-specific point sources were considered only for  
 391 the corresponding nutrient (i.e. either NO<sub>3</sub>-N or PO<sub>4</sub>-P). For diffuse sources, only N surplus data  
 392 were available and used as a descriptor for all nutrients because of expected correlations to P  
 393 surplus (Minaudo et al., 2019) and other possible interactions between the nutrient-cycles  
 394 (Gruber & Galloway, 2008). N surplus was thus considered as a proxy for agricultural, diffuse P  
 395 inputs together with the topsoil P content. All data were standardized to unit variance and zero  
 396 mean to give the variables the same prior importance and enhance the model stability (Wold et  
 397 al., 2001). Furthermore, we used simple and multiple linear regression for selected descriptors  
 398 complementing the information on variable importance and the variance explained by the  
 399 complete PLSR and RF models to explore and explain relationships between descriptors and  
 400 export metrics.

401 To assess the model performances and to tune the number of components in PLSR, we  
 402 conducted a 3 times repeated 10-fold cross-validation (for model tuning settings see Table S1).  
 403 For RF, the number of trees was set to 500 and the number of randomly sampled descriptors used  
 404 at each split was fixed to 11 based on an exemplary tuning which showed similar performances  
 405 for similar values. The variable importance of each predictor in the RF models was assessed  
 406 based on the mean increase of accuracy based on “out-of-bag” (OOB) samples from the training  
 407 process. The analysis was conducted with the *caret* package (version 6.0-84) in R (version 3.5.0)  
 408 and partial dependence plots created with the *pdp* package in R (version 0.7.0.).

409

## 410 **3 Results**

### 411 3.1. Classification of C-Q Metrics and Mean Concentrations

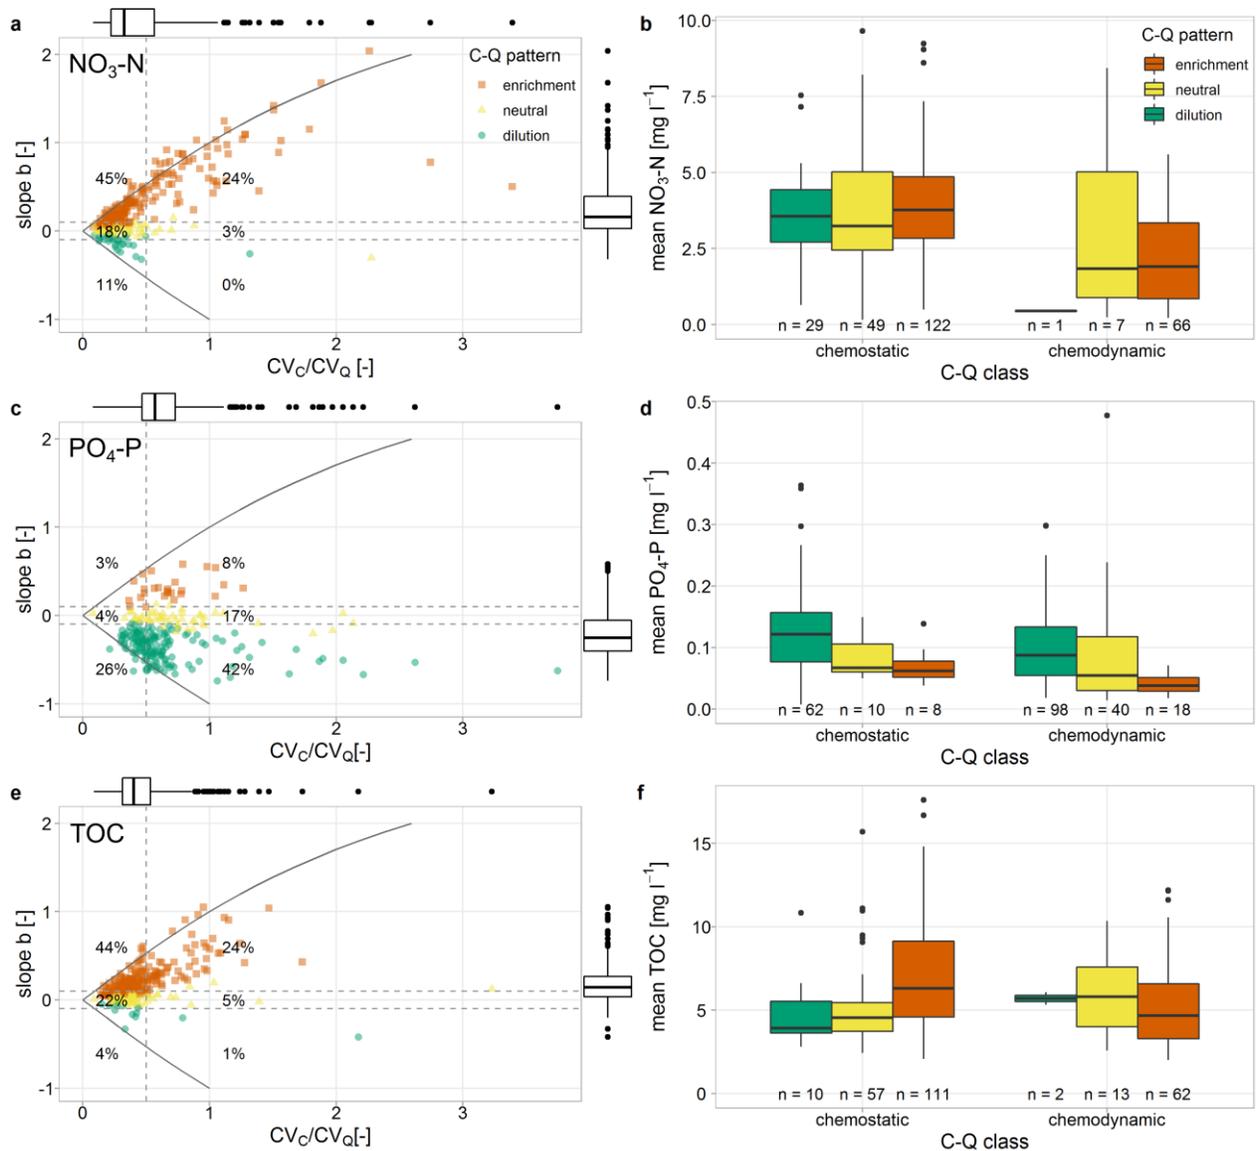

412 Basic statistics of the catchments' mean concentrations and C-Q metrics are given in  
 413 Table 2. Overall, the studied catchments showed average mean concentrations of 4.06 mg l<sup>-1</sup>  
 414 NO<sub>3</sub>-N, 0.12 mg l<sup>-1</sup> PO<sub>4</sub>-P, and 5.88 mg l<sup>-1</sup> TOC. The average coefficient of variation of  
 415 concentration CV<sub>C</sub> varied between 0.38 for NO<sub>3</sub>-N, 0.41 for TOC, and 0.68 for PO<sub>4</sub>-P. In  
 416 general, C-Q metrics covered all types of patterns and regimes with mean slope  $b > 0$  and mean  
 417  $CV_C/CV_Q < 0.5$  for NO<sub>3</sub>-N and TOC and mean slopes  $b < 0$  and mean  $CV_C/CV_Q > 0.5$  for PO<sub>4</sub>-P,  
 418 while for all nutrients standard deviations of  $b$  were larger than absolute mean  $b$ . The C-Q  
 419 power-law regressions showed nearly similar model performances for the three nutrients with  
 420 mean  $R^2 = 0.27 \pm 0.24$  for NO<sub>3</sub>-N slightly higher than PO<sub>4</sub>-P ( $R^2 = 0.21 \pm 0.19$ ) and TOC ( $R^2 = 0.19$ )

421  $\pm 0.20$ ). The highest individual  $R^2$  across the study catchments was found for TOC (maximum  
 422  $R^2=0.85$ ), closely followed by  $\text{NO}_3\text{-N}$  (maximum  $R^2=0.84$ ) and  $\text{PO}_4\text{-P}$  (maximum  $R^2=0.72$ ).

423 **Table 2.** Summary Statistics of the Calculated Metrics of Concentration (C) and Concentration-  
 424 Discharge (C-Q) Relationships.

	Concentration				C-Q relationships			
	n C-catchments with <50% censored data	Mean [mg l <sup>-1</sup> ]	Median [mg l <sup>-1</sup> ]	CV <sub>C</sub>	n C-Q-catchments with <50% (<20%) censored data	CV <sub>C</sub> /CV <sub>Q</sub>	b	R <sup>2</sup> logC-logQ
$\text{NO}_3\text{-N}$	759	4.06 $\pm$ 2.69 (3.71 $\pm$ 3.14)	3.86 $\pm$ 2.74 (3.4 $\pm$ 3.2)	0.38 $\pm$ 0.27 (0.29 $\pm$ 0.27)	275 (274)	0.47 $\pm$ 0.43 (0.33 $\pm$ 0.34)	0.26 $\pm$ 0.35 (0.16 $\pm$ 0.36)	0.27 $\pm$ 0.24 (0.22 $\pm$ 0.41)
$\text{PO}_4\text{-P}$	695	0.12 $\pm$ 0.12 (0.08 $\pm$ 0.11)	0.10 $\pm$ 0.10 (0.07 $\pm$ 0.09)	0.68 $\pm$ 0.33 (0.60 $\pm$ 0.28)	261 (236)	0.70 $\pm$ 0.42 (0.58 $\pm$ 0.31)	-0.22 $\pm$ 0.27 (-0.25 $\pm$ 0.35)	0.21 $\pm$ 0.19 (0.15 $\pm$ 0.30)
TOC	722	5.88 $\pm$ 2.96 (4.96 $\pm$ 3.35)	5.33 $\pm$ 2.81 (4.45 $\pm$ 3.19)	0.41 $\pm$ 0.16 (0.38 $\pm$ 0.17)	256 (255)	0.49 $\pm$ 0.33 (0.40 $\pm$ 0.23)	0.18 $\pm$ 0.22 (0.14 $\pm$ 0.23)	0.19 $\pm$ 0.20 (0.13 $\pm$ 0.26)

425 Note: Given are the sample sizes n and the mean  $\pm$  standard deviation of the mean and median  
 426 concentrations, the coefficients of variation of concentration CV<sub>C</sub> and the metrics of C-Q  
 427 relationships (i.e. CV<sub>C</sub>/CV<sub>Q</sub>, slope b with corresponding R<sup>2</sup>). Values in brackets refer to median  
 428  $\pm$  interquartile range.

429

430 **Figure 3.** C-Q classification schemes composed of CV<sub>C</sub>/CV<sub>Q</sub> for export regimes and slope *b* for  
 431 export patterns for NO<sub>3</sub>-N (a), PO<sub>4</sub>-P (c) and TOC (e) adapted from Musolff et al. (2015). Colors  
 432 and shape indicate the class of C-Q patterns, horizontal dashed lines approximate these class  
 433 divisions, while the vertical dashed line divides the two classes of C-Q regimes with CV<sub>C</sub>/CV<sub>Q</sub> <  
 434 0.5 for chemostatic and CV<sub>C</sub>/CV<sub>Q</sub> > 0.5 for chemodynamic regimes. The solid lines indicate the  
 435 theoretical boundaries between slope *b* and CV<sub>C</sub>/CV<sub>Q</sub> for CV<sub>Q</sub>=0.6 (after Musolff et al., 2015).  
 436 Shown percentages indicate the portion of catchments assigned to the corresponding C-Q class.  
 437 For each class mean concentrations of NO<sub>3</sub>-N (b), PO<sub>4</sub>-P (d) and TOC (f) are shown as boxplots.  
 438 n - number of observations in this class.

439 The classification of nutrient export dynamics together with mean concentrations are  
 440 shown in Figure 3.

441 For NO<sub>3</sub>-N export, the majority of catchments showed a chemostatic regime (74 %,   
 442 n = 200) and an enrichment pattern (69 %, n = 188), while 45 % combined both (see Figure 3a,  
 443 b). Highest mean concentrations were observed for chemostatic regimes, while mean

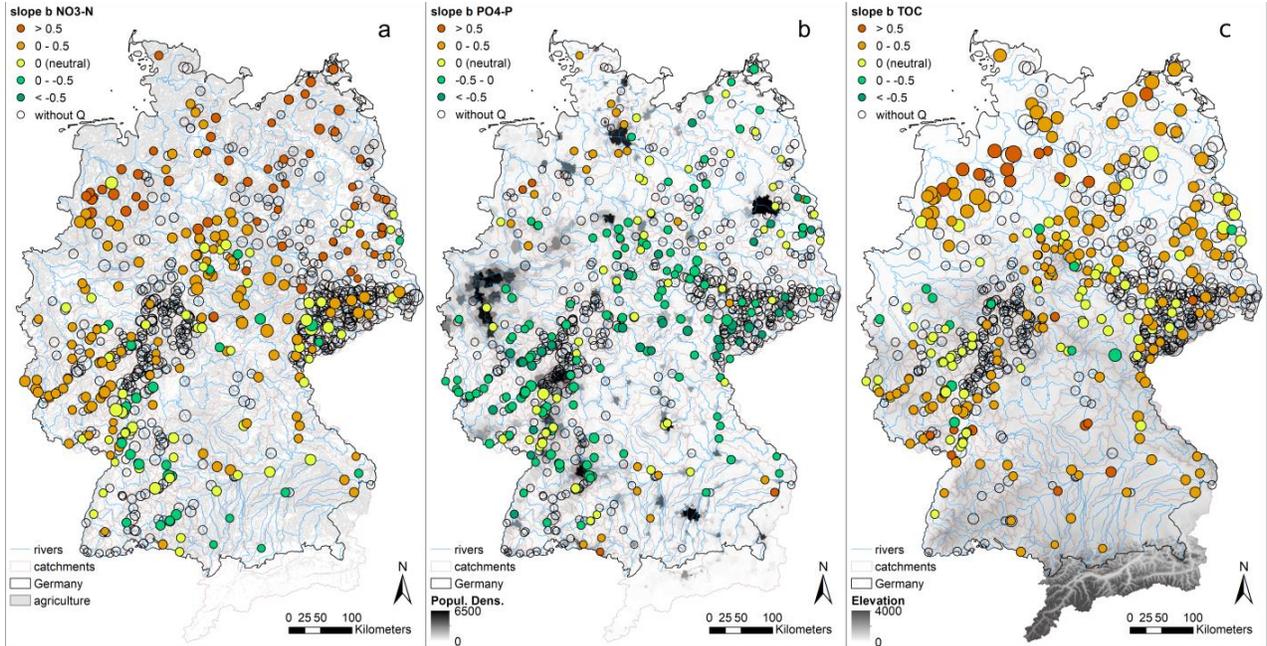

444 concentrations of the group with chemodynamic regimes were significantly lower (Kruskal-  
445 Wallis,  $p < 0.001$ ). The mean concentrations between the different C-Q patterns did not differ  
446 significantly.

447 For  $\text{PO}_4\text{-P}$  export, the majority of catchments exhibited a chemodynamic regime (67%,  
448  $n=156$ ) and a dilution pattern (68%,  $n=160$ ), while the combination of both can be found for 42%  
449 of all catchments (see Figure 3c, d). Independent of the C-Q pattern, mean concentrations were  
450 significantly lower in the chemodynamic compared to chemostatic regime (Kruskal-Wallis,  
451  $p < 0.001$ ). Among the C-Q patterns, mean concentrations were significantly higher for dilution  
452 patterns compared to neutral (Wilcoxon,  $p = 0.002$ ) and to enrichment (Wilcoxon,  $p < 0.001$ )  
453 patterns. Catchments with enrichment patterns showed the lowest mean concentrations though  
454 they were not significantly different from catchments with neutral C-Q patterns (Wilcoxon,  
455  $p = 0.057$ ).

456 For TOC, chemostatic export (70 %,  $n= 178$ ) and enrichment patterns (68 %,  $n = 173$ )  
457 prevailed with 44% of the catchments combining both (see Figure 3e, f). Overall, the  
458 chemostatic regime showed significantly higher mean TOC concentrations than the  
459 chemodynamic regimes (Kruskal-Wallis,  $p = 0.014$ ). The mean concentrations between the C-Q  
460 patterns also differed significantly (Kruskal-Wallis,  $p = 0.007$ ). The catchments with enrichment  
461 patterns had significantly higher mean concentrations than those exhibiting neutral C-Q patterns  
462 (Wilcoxon,  $p = 0.011$ ), which was mainly apparent within the chemostatic regime (see Figure  
463 3f).

### 464 3.2. Spatial Patterns of Concentrations and Export Dynamics

465 The spatial organisation of mean concentrations and export patterns of each nutrient are  
466 shown in Figure 4. For all nutrients, regional clusters of the export patterns can be observed.  
467  $\text{NO}_3\text{-N}$  showed the strongest enrichment patterns in Northern Germany and some dilution  
468 patterns in South-West Germany. The highest mean  $\text{NO}_3\text{-N}$  concentrations were found in the  
469 Eastern part of Germany. TOC also showed strong enrichment patterns in Northern Germany,  
470 esp. in the North-West, but also in the South of Germany, while the small amount of dilution  
471 patterns seemed to cluster more in the Central-West. The highest mean TOC concentrations were  
472 found in the lowlands in Northern, esp. North-Western Germany coinciding with the enrichment  
473 patterns. For  $\text{PO}_4\text{-P}$ , the few enrichment patterns clustered in the North-West and South-East of  
474 Germany. Highest mean  $\text{PO}_4\text{-P}$  concentrations were found in Central-Germany, though a general  
475 spatial organisation was not obvious for this metric.

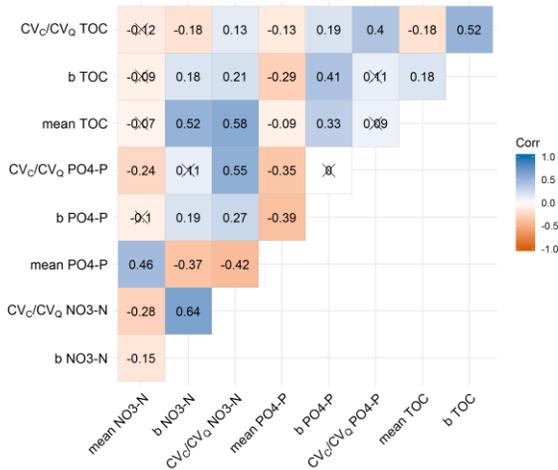

476

477 **Figure 4.** Spatial patterns of C-Q slope b across Germany with point size relative to mean  
 478 concentrations (scaled to the respective range) for NO<sub>3</sub>-N (a), PO<sub>4</sub>-P (b), and TOC (c).

479

### 3.3. Relationships Among the Nutrient Export Metrics

480

481 **Figure 5.** Spearman rank correlation matrix between metrics of the export regimes. Crosses  
 482 mark non-significant correlations (significance level of 0.05)

483 To describe interactions between the three major nutrients, we quantified the  
 484 interdependencies between the water quality metrics using spearman rank correlations (Figure 5).  
 485 For NO<sub>3</sub>-N and PO<sub>4</sub>-P, all metrics correlated positively, which was strongest for CV<sub>C</sub>/CV<sub>Q</sub>  
 486 (r=0.55) and lowest for slope b (r=0.19). For NO<sub>3</sub>-N and TOC, mean TOC correlated positively  
 487 with the NO<sub>3</sub>-N export metrics (CV<sub>C</sub>/CV<sub>Q</sub> r=0.58 and slope b r=0.52), which was also apparent  
 488 for the respective TOC export metrics but less pronounced. For PO<sub>4</sub>-P and TOC, slope b of PO<sub>4</sub>-  
 489 P correlated positively and mean PO<sub>4</sub>-P concentration negatively with all TOC metrics, with the

490 correlation coefficient between the slopes  $b$  being the highest ( $r=0.41$ ). This was similar to the  
491 correlation coefficient between the  $CV_C/CV_Q$  of  $PO_4\text{-P}$  and TOC ( $r=0.4$ ).

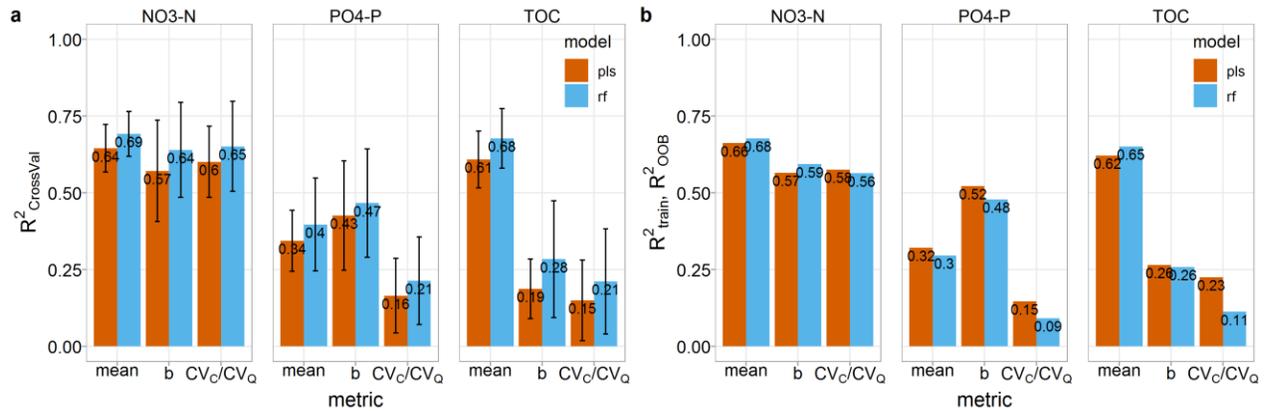

### 492 3.4. Linking Export Metrics to Catchment Characteristics

493 Several co-linearities exist among the catchment characteristics quantified for all  
494 variables by Spearman rank correlations (for correlation matrix see Figure S3). The land cover  
495 classes fraction of agriculture and forest were strongly negatively correlated as opposing land use  
496 classes. Agricultural land fraction also correlated negatively with the topographic slope, water  
497 available in the root zone, the C/N ratio and N content in the topsoil and positively with N  
498 surplus and soil P content. The topographic variables were strongly correlated among themselves  
499 such that higher slopes prevailed in higher elevations and linked to lower TWI. Topography  
500 variables also correlated with descriptors of climate and hydrology (e.g., higher topographic  
501 slopes related to higher precipitation amount and frequency, specific discharge, runoff  
502 coefficient and discharge variability but lower aridity index), lithology (e.g., higher slopes  
503 related to lower fractions of sedimentary aquifers and lower depth to bedrock), soil chemistry  
504 (e.g., higher slopes related to higher N in the topsoil but less P) and source heterogeneity (e.g.,  
505 higher slopes related to lower mean source distances to stream and lower vertical concentration  
506 contrasts). This means that flat lowland catchments tend to have more agriculture and diffuse  
507 sources, more sedimentary aquifers with deeper bedrock, more riparian wetlands and more  
508 vertical concentration contrasts but lesser precipitation and lesser discharge.

509 Correlations between the response metrics and individual catchment characteristics are  
510 given in the Figure S4. They provide a first indication of existing links between the  
511 characteristics and the responses, e.g. between the topography and the mean TOC concentration  
512 and the C-Q relation metrics of  $NO_3\text{-N}$ . Yet, due to correlations among several descriptors  
513 suitable multivariable statistical approaches were required for interpretation of linkages and  
514 hierarchies (see Section 2.4) of which the results are presented in the following section.

#### 515 3.4.1. Predictive Power of Descriptors for Response Variables

516 The descriptor variables for horizontal source heterogeneity ( $sdist\_mean$ ,  $het\_h$ ) did  
517 neither prove to be among the significant predictors nor improve the model performances of the  
518 PLSR and RF models (PLSR and RF results presented in Table S3-S4) nor correlate strongly  
519 with the export metrics (Figure S4). As missing values for these variables, described earlier in  
520 Section 2.3, reduced the overall number of catchments usable for PLSR and RF, we decided to  
521 redo the analysis with the bigger sample size excluding these variables. The set of catchments  
522 presented in Section 2.3 and results consistently refer to this larger selection.

523

524 **Figure 6.** PLSR and RF model performances as mean  $R^2$  of the cross-validation with error bars  
 525 indicating the standard deviations among the 30 cross-validation folds (a) and of the trained  
 526 models calculated from out-of-bag samples for RF (b).

527 The variability in the C-Q metrics could be explained by the catchment characteristics,  
 528 however, to different degrees depending on the nutrient types and their descriptive metrics  
 529 (Figure 6). The mean  $R^2$  in cross-validation were consistently higher for the RF models, but not  
 530 substantially, considering the apparent variability between the different folds. The model  
 531 performances of the trained models,  $R^2_{\text{train}}$  for PLSR and  $R^2_{\text{OOB}}$  for RF models, generally reached  
 532 similar levels compared to the cross-validation. Note that the  $R^2_{\text{OOB}}$  is calculated based on out-  
 533 of-the-bag samples in the RF models and thus not directly comparable to  $R^2_{\text{train}}$  of the PLSR  
 534 models.

535 All three NO<sub>3</sub>-N metrics could be predicted with a reasonably good cross-validated  
 536 performance,  $R^2_{\text{CrossVal}} > 0.5$  with the highest value being  $R^2_{\text{CrossVal}} = 0.69$  for mean NO<sub>3</sub>-N  
 537 concentrations with RF. For PO<sub>4</sub>-P, performance is substantially lower. Models for mean  
 538 concentrations reached  $R^2_{\text{CrossVal}} > 0.3$  and slope b  $R^2_{\text{CrossVal}} > 0.4$ , while the models CV<sub>C</sub>/CV<sub>Q</sub>  
 539 of PO<sub>4</sub>-P only reached  $R^2_{\text{CrossVal}} < 0.3$ . For TOC, mean concentrations were well explained with  
 540  $R^2_{\text{CrossVal}} > 0.5$ , while the C-Q metrics CV<sub>C</sub>/CV<sub>Q</sub> and slope b in contrast only reached  
 541  $R^2_{\text{CrossVal}} < 0.3$ . The model results provide variable importance measures that allow ranking the  
 542 descriptive power of the catchment characteristics within the explained variability of the  
 543 response (Table 3 presents variables with highest ranks, Table S5-S7 the complete results). For  
 544 models with low overall explained variability the interpretation of variable importance is very  
 545 limited though.

546 For mean NO<sub>3</sub>-N concentrations, both PLSR and RF models rank the fractions of forest  
 547 highest relating to low diffuse inputs, followed by agricultural land cover and top soil C/N ratio  
 548 in PLSR and mean annual precipitation and its seasonality in RF. In the PLSR model, there is a  
 549 prominent difference in variable importance to the next descriptors vertical source heterogeneity,  
 550 fraction of sand and clay (all three with a positive direction of influence) and the fraction of  
 551 sedimentary aquifer. The RF model marks a step in variable importance after the first ranked  
 552 fraction of forest, which is followed by mean annual precipitation and its seasonality, fraction of  
 553 sedimentary aquifer, mean vertical heterogeneity and the fraction of agriculture on rank 6. For  
 554 explaining the NO<sub>3</sub>-N dynamics (b and CV<sub>C</sub>/CV<sub>Q</sub>) the descriptor vertical heterogeneity has the  
 555 highest importance (ranks highest in three of the four models). The PLSR model coefficients  
 556 indicate a positive link meaning that the slope b tends to be higher in areas with high vertical

557 contrast between potential seepage and groundwater NO<sub>3</sub>-N concentrations. Only the RF model  
558 ranks the topographic descriptors (slope\_mean, twi\_mean, dem\_mean) highest for the slope b of  
559 NO<sub>3</sub>-N, which also appear relatively high ranked in the other three models for NO<sub>3</sub>-N export  
560 dynamics following het\_v. The variables depth to bedrock (dtb) and fraction of sedimentary  
561 aquifer (f\_sedim) also obtain high importance values.

562 For mean PO<sub>4</sub>-P concentrations, the P load from point sources stands out with the highest  
563 variable importance in both models and a large step to the second ranked variables. Slope b of  
564 the C-Q relationship is explained the most by mean N surplus (N\_surp\_00 and N\_surp\_80) and  
565 the fraction of sedimentary aquifers, all with a positive relation to b. After a step in variable  
566 importance, these three variables are followed by the 90th percentile of the TWI, the P content in  
567 the topsoil and the precipitation frequency, amount and seasonality.

568 Mean TOC concentrations are explained the most by the TWI (90 percentile and mean)  
569 based on PLSR and by mean elevation and topographic slope based on RF. The other respective  
570 topographic variables as well turn out highly ranked in the other model together with the fraction  
571 of sedimentary aquifers, potential evapotranspiration and depth to bedrock.  
572

575 Note: Only the six highest ranked variables are shown, the complete results are given in Table S6-8 in the  
 576 supporting information. CrossVal - cross-validation; OOB – out-of-bag samples; VIP - variable influence on  
 577 projection of PLSR; Imp – variable importance in RF models.

578

579 **4 Discussion**

580 4.1. Nutrient-Specific Export and Controls

581 4.1.1. NO<sub>3</sub>-N: Natural Attenuation Buffers Input and Controls Export Regimes

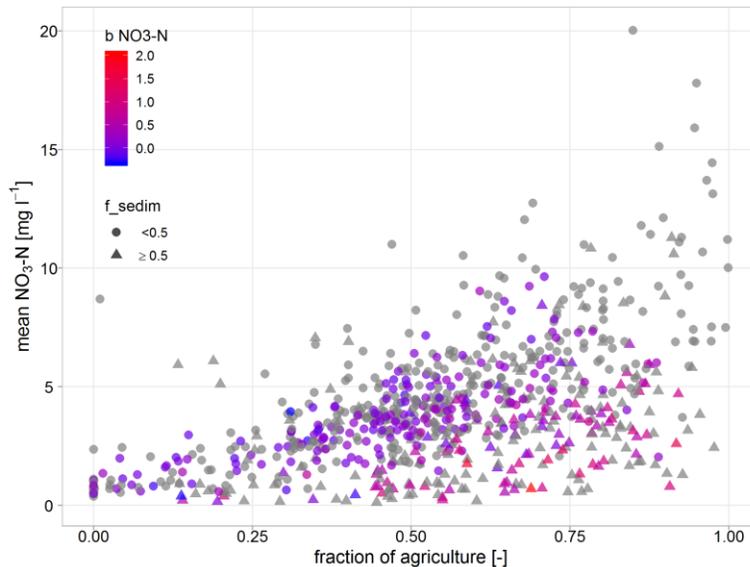

582 For NO<sub>3</sub>-N export in the study catchments, we found a dominance of enrichment patterns  
 583 and chemostatic regimes and significantly higher mean concentrations for chemostatic compared  
 584 to chemodynamic regimes.

585 The variability in mean NO<sub>3</sub>-N concentrations among the studied catchments was linked  
586 to the land use as the fractions of forest and of agriculture both ranked high in the PLSR and RF  
587 models and relate to low and high diffuse N sources, respectively. The fraction of either forest or  
588 agriculture alone could explain 32% or 29% of this variability in a simple linear regression  
589 respectively, while in the PLSR and RF the total variability explained by all descriptors was 64  
590 to 70%. Interestingly, the N surplus could only explain 3.5% for N\_surp\_00 and 6.4% for  
591 N\_surp\_80 in a simple linear model even though it is strongly related to agricultural land  
592 (f\_agric and N\_surp\_00 r=0.58, and N\_surp\_80 r=0.71, spearman rank, Figure S3). Probably,  
593 this is related to a few catchments with exceptionally high N surplus but moderate mean NO<sub>3</sub>-N  
594 concentrations.

595 However, the relationship between the fraction of agriculture and the mean NO<sub>3</sub>-N  
596 concentration is highly heteroscedastic as shown in **Figure 7**. We found that deviations from a  
597 positive linear relationship between N input and N output are related to soil and aquifer  
598 properties as e.g. f\_sedim ranked high in the PLSR and RF (Table 3 and S5), which could  
599 indicate buffering of inputs by natural attenuation (removal by denitrification). Adding the  
600 fraction of sedimentary aquifer as a secondary factor to the linear model with forest (or  
601 agriculture) fractions increased the explained variability to 52% (or 49%) respectively. Previous  
602 studies have shown that sedimentary aquifers often exhibit high denitrification potential  
603 (Hannappel et al., 2018; Knoll et al., 2020; Kunkel et al., 2004). Unconsolidated aquifers are  
604 usually deep low-land aquifers linked to long travel times (Merz et al., 2009; Wendland et al.,  
605 2008) with anaerobic conditions, organic carbon or pyrite deposits providing electron donors for  
606 denitrification, especially in the lowlands of Northern Germany (Kunkel et al., 2004; Wendland  
607 et al., 2008). Both long residence times and favourable conditions for denitrification increase the  
608 potential for NO<sub>3</sub> removal along the flow path (Rivett et al., 2008). This link is supported by  
609 het\_v, ranked 4<sup>th</sup> and 5<sup>th</sup>, which represents the vertical concentration contrast, likely resulting  
610 from denitrification under anaerobic subsurface conditions (Knoll et al., 2020) and correlating  
611 positively with f\_sedim (r=0.68). Denitrification in riparian wetlands, more abundant in  
612 lowlands, could additionally buffer NO<sub>3</sub>-N inputs and create a link to the carbon cycle (see also  
613 Section 4.2) (Lutz et al., 2020; Pinay et al., 2015; Sabater et al., 2003). Instead of effective N  
614 removal by denitrification, the decrease in concentration could also be linked to the large  
615 groundwater storages of deep sedimentary aquifers causing high dilution by old (pre-industrial)  
616 water fractions low in NO<sub>3</sub>-N concentrations and resultant vertical concentration contrasts. In  
617 this case, the system would not be equilibrated in terms of its N balance within the investigated  
618 time frame (Ehrhardt et al., 2019). Additionally, instream retention could also be higher in areas  
619 with low slopes due to longer residence times in the river network.

620 As a third component and climatic driver, the seasonality of precipitation could slightly  
621 increase the variability of mean NO<sub>3</sub>-N explained to R<sup>2</sup> = 55% in combination with f\_forest  
622 (53% with f\_agric) in a linear regression though the high ranking in RF but not in PLSR suggests  
623 rather a non-linear relation. Higher precipitation seasonality P\_SIs<sub>w</sub>, i.e. higher summer to  
624 winter precipitation, was linked to higher mean NO<sub>3</sub>-N. Possibly, areas with higher P\_SIs<sub>w</sub> have  
625 a lower dilution potential of NO<sub>3</sub>-N loads especially during winter, typically the season of high  
626 riverine NO<sub>3</sub>-N concentration. Moreover, high P\_SIs<sub>w</sub> prevail in areas of lower mean  
627 precipitation P\_mm (r=-0.51, spearman rank) and higher aridity index (AI; r=0.49) decreasing  
628 the overall hydro-climate related dilution potential.

629 Altogether, this clearly indicates that the anthropogenic N-input from diffuse sources is a  
 630 first order control for mean  $\text{NO}_3\text{-N}$  concentrations observed in the surface water, while natural  
 631 attenuation is able to buffer the high inputs especially in lowlands with deep aquifers, whereas  
 632 hydroclimatic conditions seem to play a subordinate role.

633

634 **Figure 7.** Relation between the fraction of agriculture as diffuse source of N, mean  $\text{NO}_3\text{-N}$   
 635 concentrations. Colors indicate the slope  $b$  of C-Q relationship and the shape indicates if  
 636 sedimentary aquifer type dominates.

637 In this study, high mean  $\text{NO}_3\text{-N}$  were often combined with low concentration variability  
 638 (**Figure 3**), i.e. chemostatic regimes ( $\text{CV}_C/\text{CV}_Q < 0.5$ ), and neutral C-Q patterns ( $b \approx 0$ ). This  
 639 finding agrees with Thompson et al. (2011) who found significantly lower  $\text{CV}_C/\text{CV}_Q$  for the  
 640 group of catchments with higher  $\text{NO}_3\text{-N}$  export and hypothesized that such behaviour was due to  
 641 homogenization of sources. Minaudo et al. (2019), on the other hand, found that the background  
 642 pollution level, an indicator for mean  $\text{NO}_3\text{-N}$  concentrations, was positively correlated to the  
 643 seasonal  $\text{NO}_3\text{-N}$  dynamics (i.e. slope  $b$ ). This study disagrees with the hypothesis that highly-  
 644 managed, agricultural catchments are subject to homogenization of sources and thus to  
 645 chemostatic export regimes (Basu et al., 2010) as high fractions of agriculture did not induce  
 646 chemostasis and neutral C-Q patterns. Instead, many agriculture dominated catchments exhibited  
 647 chemodynamic export with enrichment patterns and relatively low mean concentrations (**Figure**  
 648 **7**). These chemodynamic catchments widely coincided with catchments where sedimentary  
 649 aquifers and strong vertical concentration heterogeneity prevailed.

650 The variability in the export dynamics, i.e. regimes and patterns, were mostly explained  
 651 by and positively linked to the descriptor  $\text{het}_v$  representing the average vertical  $\text{NO}_3\text{-N}$   
 652 heterogeneity from soils to groundwater within each catchment. In contrast, the variables of  
 653 horizontal source heterogeneity  $\text{het}_h$  and  $\text{sdist\_mean}$  did not show a dominant effect. This  
 654 means the larger the downward concentration decrease is over depth, the more dynamic and  
 655 enriching  $\text{NO}_3\text{-N}$  is exported, and the smaller the gradient, the more chemostatic the export.  
 656 Accordingly, our results from data-driven analysis over a wide range of catchments confirm  
 657 findings from previous modeling studies: Zhi et al. (2019) found vertical concentration gradients  
 658 resulting from source distributions and reactions in combination with end-member mixing and

659 Musolff, Fleckenstein, et al. (2017) found the concentration gradient over travel times as a more  
660 general, indirect measure of solute source heterogeneity to control C-Q patterns. The linkage  
661 between vertical concentration heterogeneity and export patterns seems plausible, as agricultural  
662 and atmospheric N input enter the subsurface from the top. A top-loaded profile in combination  
663 with the dominance of young water contribution to discharge from upper soil layers during high  
664 flows, and dominance of old water fractions at base flow conditions (exponential saturated  
665 hydraulic conductivity profile) causes a positive C-Q slope. This interpretation coincides with  
666 the concept of juxtaposition of discharge generation and concentration profiles by Seibert et al.  
667 (2009) and with the scenario of higher concentrations linking to shorter travel times in Musolff,  
668 Fleckenstein, et al. (2017). On a longer term, the concentration gradient will only be retained  
669 when subsurface attenuation occurs. Note that if discharge generating zones are stationary over  
670 time, chemostasis can also be generated from a heterogeneous profile.

671 We found that the interaction between diffuse input and reactivity, more specifically the  
672 combined effect of reaction rates and residence times along the flow paths resulting in NO<sub>3</sub>-N  
673 attenuation, might determine the strength of vertical concentration heterogeneity. Consequently,  
674 chemodynamic export with enrichment patterns could indicate natural attenuation and effective  
675 denitrification under high inputs. In consequence, chemostasis would be rather explained by  
676 missing reactivity of the catchment than by the existence of large legacy N pools in the  
677 catchments, as previously suggested (Basu et al., 2010), although both may co-exist.  
678 Chemodynamic export may also occur when vertical concentration contrasts emerge from the  
679 existence of NO<sub>3</sub>-N poor older water fractions in large and deep groundwater bodies. The  
680 consistent relationship between input, attenuation and export patterns (**Figure 7**) also suggests  
681 that catchments with relatively low mean NO<sub>3</sub>-N concentrations but high inputs and steep  
682 positive C-Q patterns might still be “hot spots” in terms of exported loads, eutrophication risk,  
683 and large N legacies. Here, the natural attenuation might effectively buffer inputs in terms of  
684 mean riverine and groundwater concentrations but not necessarily the exported loads during  
685 high-flows. The denitrification capacity could however decrease or exhaust over time when  
686 electron donors are consumed, which has been discussed, for example, by Wilde et al. (2017)  
687 and Hannappel et al. (2018). Additionally, tile drainages can enhance the effect of concentration  
688 heterogeneity by increasing the younger water during high-flows and avoiding potential retention  
689 zones (Musolff et al., 2015; Van der Velde et al., 2010; Van Meter & Basu, 2017). As  
690 geoinformation on drainages over this large scale is not available we cannot prove the role of this  
691 additional flow path in this study. Still, drainage systems are the main delivery pathway of N into  
692 surface waters in Mecklenburg-Vorpommern contributing 70% of the total N input (Kunkel et  
693 al., 2017) and widely spread in Germany (Behrendt, 1999) (see also Section 4.1.2).

#### 694 4.1.2. PO<sub>4</sub>-P: Unexpected Dominant Control of Diffuse Sources on Export Patterns

695 For PO<sub>4</sub>-P export, dilution patterns with chemodynamic regimes prevailed (42% of the  
696 study catchments), while the dilution group had the highest mean concentrations. Mean PO<sub>4</sub>-P  
697 concentrations were positively linked to direct anthropogenic input from point sources to the  
698 streams although, surprisingly, overall explained variance in the PLSR and RF models was low  
699 ( $R^2_{\text{CrossVal}} = 0.34$  and  $0.40$ ). A linear regression of mean PO<sub>4</sub>-P and P\_WW confirmed that its  
700 descriptive power was weak ( $R^2 = 11\%$ ). In combination with a second variable, selected based  
701 on rankings in PLSR and RF models, the linear models with the topsoil C/N ratio explained 20%  
702 (soil\_CN) and with a climatic descriptor explained 19% (AI), 18% (T\_mean) and 17%  
703 (PET\_mm). Previous studies also state the dominant role of point sources for average riverine

704 total P concentrations (Minaudo et al., 2019; Westphal et al., 2019; Withers & Jarvie, 2008),  
705 with contributions remaining high even after significant reductions of inputs from point sources  
706 (Behrendt, 1999; Westphal et al., 2019).

707 In general, PO<sub>4</sub>-P is subject to P cycling caused by highly dynamic, small-scale biotic and  
708 abiotic processes, including retention and remobilization processes in the stream (Withers &  
709 Jarvie, 2008). By this, P cycling potentially reshapes direct inputs and delivery from land-stream  
710 transfer at catchment scale. This could explain that mean PO<sub>4</sub>-P concentrations are linked to the  
711 inputs but hardly predictable by average catchment characteristics because factors affecting  
712 instream nutrient retention, transformation and remobilization are not adequately represented  
713 (Withers & Jarvie, 2008; Withers et al., 2012). These factors include physico-chemical and  
714 biological controls such as redox conditions, mineral precipitation and dissolution, water  
715 temperatures, river bed morphology and biological uptake and mineralisation, which may vary  
716 strongly in space and time (Withers & Jarvie, 2008). Other reasons could be uncertainties related  
717 to (1) the point source data disregarding potential intra- and interannual variability, or (2) the  
718 sampling frequency of C potentially missing moments of peak concentrations and leading to  
719 underestimation of mean PO<sub>4</sub>-P, as noted by e.g. Hunsaker and Johnson (2017).

720 For PO<sub>4</sub>-P export dynamics, dilution patterns prevailed in two thirds of the catchments  
721 which agrees with previous studies and has usually been associated with point-source dilution  
722 (Dupas, Gascuel-Oudou, et al., 2015; Moatar et al., 2017; Musolff et al., 2015) or  
723 biogeochemical processes releasing PO<sub>4</sub>-P during summer low-flows and thus mimicking point  
724 sources (Dupas et al., 2018). Enrichment patterns of PO<sub>4</sub>-P, which have been found in just 11%  
725 of the catchments, have also been observed in other cases, e.g. during storm events in  
726 agricultural settings by Rose et al. (2018) and Bieroza and Heathwaite (2015), who explain this  
727 by dominance and mobilization of diffuse sources. Similar behaviour was noticed in forested  
728 catchments by Hunsaker and Johnson (2017), who explain the PO<sub>4</sub>-P enrichment by mobilization  
729 from a nutrient-rich O-horizon under high-flows linking soil to water chemistry.

730 Interestingly, even with prevailing dilution patterns, not the amount of point source  
731 derived P in the catchment, but instead the N surplus and fraction of sedimentary aquifers turned  
732 out to be the most dominant predictive variables and were positively linked to slope b. Both  
733 variables together explain 42% of the variability in slope b of PO<sub>4</sub>-Q relationships in a linear  
734 model, and individually 27% and 26% respectively. This constitutes a large part of the explained  
735 variability of all descriptors ( $R^2_{\text{CrossVal}}$  spans 0.43-0.47). This high relatively predictive power of  
736 N surplus is explained by the catchments with very high N surplus exhibiting positive C-Q  
737 relationships.

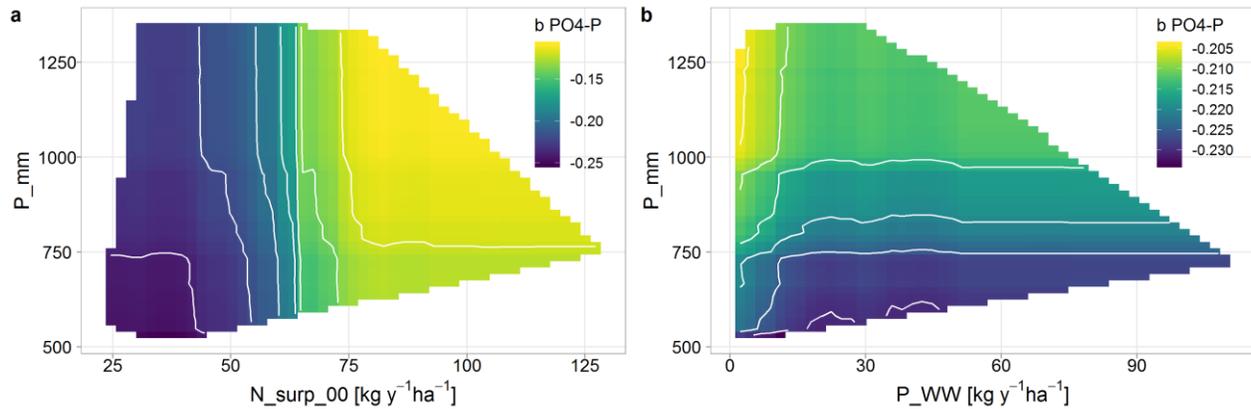

738 Especially in North-West and South-East Germany, catchments with high N surplus  
739 tended to show enrichment patterns for PO<sub>4</sub>-P (Figure 4), i.e. higher PO<sub>4</sub>-P concentrations with  
740 higher discharge. High P applications, especially from manure, and low P use efficiencies have  
741 led to widespread P accumulation on agricultural soils increasing the risk of P losses (Schoumans  
742 et al., 2015). Sharpley et al. (2013) explain that P legacies can cause saturation of soil sorption  
743 capacities resulting in P mobilization in contrast to the usual predominance of the solid phase  
744 and sorption. In field experiments, Hahn et al. (2012) observed that manure applications and soil  
745 P status additively increased diffuse P losses. As areas with prevailing enrichment patterns  
746 coincide with regions of intense manure applications from livestock farms (Häußermann et al.,  
747 2019) and high degrees of P saturation (Fischer et al., 2017), they are probably the reason for the  
748 enhanced PO<sub>4</sub>-P land-to-stream transfer. This is supported by the PLSR model in which topsoil P

749 content (soil\_P) links positively to slope b and ranks order 5. Fischer et al. (2017) found  
750 widespread (>76%) high risks of dissolved P loss from German agricultural soils, so that this  
751 process of diffuse P mobilization is likely to occur in more than 11% of the catchments but might  
752 be less dominant in catchments where dilution prevails.

753 Tile drainages and preferential flow paths can enhance P transfer to streams because P  
754 from upper soil layers can bypass the potential sinks in the soil matrix and P accumulation can  
755 additionally be enhanced along those flow paths (Sharpley et al., 2013). Tile drainage can  
756 increase exported P (Rozemeijer et al., 2010) and cause positive PO<sub>4</sub>-Q relationships (Gentry et  
757 al., 2007). This means that tile drainages have the potential to translate existing spatial source  
758 heterogeneity between top and deeper soil and aquifer layers into stream water quality dynamics  
759 by avoiding reactive zones and that this mechanism could be activated before widespread soil P  
760 saturation. Artificial drainages are likely to be present in those parts of Germany to facilitate  
761 agricultural production on flat areas and relatively wet soils, which might partly be related to the  
762 high ranks of f\_sedim and twi\_90p with positive coefficients in the PLSR. For Germany, the  
763 fraction of artificially drained areas of agricultural land has been estimated to 12.4% (Behrendt,  
764 1999), while the fractions can be higher in single catchments, especially in the north western  
765 Germany with e.g. 41% in the Weser catchment (Tetzlaff et al., 2009), but also in eastern  
766 Germany e.g. 21.7% in the Mulde catchment (Behrendt, 1999).

767 Assuming that N surplus and top soil P represent diffuse anthropogenic P inputs, our  
768 PLSR and RF results suggest that P mobilization is facilitated by diffuse P inputs, high degrees  
769 of P saturation and potentially preferential flowpaths, including artificial drainage systems, and is  
770 likely to cause the observed enrichment patterns and be a dominant process in agricultural  
771 landscapes. P saturation in the topsoil can be considered as source heterogeneity with a top-  
772 loaded profile.

773 Climatic controls were also identified and ranked relatively high in both PLSR and RF  
774 models, e.g. mean annual precipitation showed a positive impact on slope b (Figure 8, Table 3).  
775 The PLSR and RF models including hydrological descriptors indicate that a higher seasonal Q  
776 ratio (seasRQ  $\approx$  1, i.e. higher summer compared to winter Q and more equilibrated Q  
777 seasonality) relates to a higher slope b and takes over the rank of P in these models (Table S7).  
778 This suggests that the impact of higher P is related to a higher dilution potential especially during  
779 the summer low-flow period. A higher summer discharge causes lower concentrations during  
780 low-flow period and thus less PO<sub>4</sub>-P dilution export patterns. In general, high precipitation  
781 amounts could also favour reducing conditions for PO<sub>4</sub>-P mobilization or a higher potential of  
782 land-stream transfer of diffuse P sources especially during high-flows. Though the latter is not  
783 apparent in the data as extreme seasonality with relatively high winter Q (seasRQ  $\ll$  1) should  
784 then enhance enrichment patterns, but higher seasRQ and P consistently link to higher slope b  
785 values. The climatic dilution component creates additional variability between sources and  
786 exported concentrations.

787

788 **Figure 8.** Partial dependence plots for RF model for slope  $b$  of  $\text{PO}_4\text{-P}$  showing the interaction  
 789 between a) N surplus ( $N_{\text{surp\_00}}$ ) and b) P loads from point sources ( $P_{\text{WW}}$ ) with mean annual  
 790 precipitation ( $P_{\text{mm}}$ ). Colors indicate the range of predicted  $b$  values with mean values for the  
 791 other descriptors. White areas are outside the covered parameter space (without extrapolation).

792 Figure 8 confirms that the impact of N surplus on slope  $b$  exceeds the impact of point  
 793 sources and climatic drivers (as indicated by the steeper color gradient and value range in panel  
 794 a). The impact of point sources is slightly visible for low loads suggesting slight threshold  
 795 behaviour (Figure 8b): if there is any point source in the catchment, slope  $b$  tends to be smaller,  
 796 i.e. more dilution patterns, while the magnitude of the source seems to be less important and the  
 797 effect relatively weak.

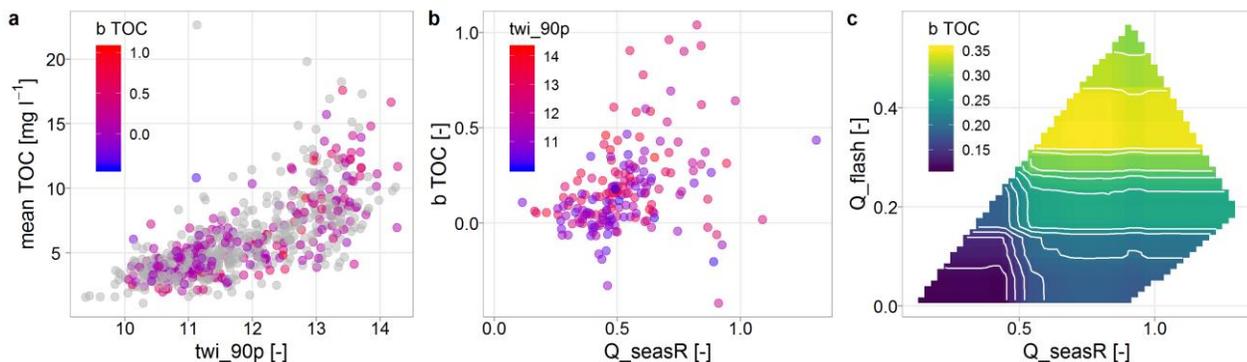

798 All in all, the fact that slope  $b$  correlates negatively with mean  $\text{PO}_4\text{-P}$  concentrations ( $r=-$   
 799  $0.39$ , spearman rank, see Figure 5) and with point sources ( $r=-0.2$ , spearman rank, Figure S4)  
 800 while point sources partly explain mean concentrations, suggests that point sources still influence  
 801  $\text{PO}_4\text{-P}$  export dynamics even though their link is not strong. This fits to the hypothesis that P  
 802 cycling significantly reshapes P responses by decoupling  $\text{PO}_4\text{-P}$  concentrations from Q while  
 803 keeping the  $\text{PO}_4\text{-P}$  variability high, leading to the poor explanatory power of point sources and  
 804 other averaged catchment characteristics used in this study. Moreover, point source inputs could  
 805 be decoupled stronger than diffuse inputs because P cycling is likely more pronounced and  
 806 variable during summer. This could be the reason why point sources have an influence on export  
 807 patterns and dilution patterns prevail even though diffuse sources explain the overall variability  
 808 of slope  $b$  better because the highest N surplus values relate to observed enrichment patterns.

#### 809 4.1.3. TOC: Flat Topography Strengthens Sources and Hydrology-Driven Export

810 Topography related characteristics appeared to dominantly control mean TOC, as the  
 811 TWI and the topographic slope turned out to be the dominant descriptors in PLSR and RF  
 812 models with similar variable importance. The 90 percentile and the mean of TWI were good  
 813 predictors, each alone explaining 52% of the variability in a linear model, while the mean  
 814 elevation and slope ranked highest in the RF model, they explain less variability in a linear  
 815 model (33 and 38% respectively). This topography control agrees with previous results by  
 816 Zarnetske et al. (2018) who found the topographic slope and the share of wetlands followed by  
 817 mean annual precipitation to best predict DOC concentrations levels in the contiguous US.  
 818 Recently, Musloff et al. (2018) also found the 90 percentile of the TWI as a good predictor for  
 819 median DOC concentrations in small mountainous, mainly forested German catchments. The 90

820 percentile of the TWI can also be interpreted as proxy for the extent of riparian wetlands  
 821 (Musolff et al., 2018), source areas of organic matter and thus TOC. Higher  $twi_{90p}$  link to  
 822 higher but also more variable mean TOC concentrations, resembling a heteroscedastic  
 823 relationship (**Figure 9a**), similar to results by (Musolff et al., 2018) and over a wider range of  
 824 topographic settings as presented in Musolff et al. (2015).

825 For TOC export, most catchments classified as enrichment patterns and chemostatic  
 826 regimes. The dominance observed across Germany agrees with previous studies on the  
 827 dominance of enrichment patterns and transport-limited export for DOC and TOC (Moatar et al.,  
 828 2017; Musolff et al., 2018; Musolff et al., 2015; Zarnetske et al., 2018). Zarnetske et al. (2018)  
 829 found wetland cover to control this patterns, while Musolff et al. (2018) found high  $twi_{90p}$ ,  
 830 soluble reactive phosphorus, pH and AI to relate to high C variability (as interquartile C range).  
 831 The observed variability in the export metrics as noticed over the large set of study catchments  
 832 could not be explained satisfactorily ( $R^2_{CrossVal} \leq 0.28$ ) by the used characteristics, which include  
 833 the fraction of wetland, the  $twi_{90p}$  and climatic characteristics. In Moatar et al. (2017), DOC-Q  
 834 slopes correlated with various hydrological variables and, in Musolff et al. (2015), the variability  
 835 in TOC dynamics were explained well by the BFI (+), artificial drainages (-) and topographic  
 836 slope (+). In agreement, including the hydrological parameters as descriptors (Table S11)  
 837 substantially increased the variance explained by the PLSR and RF models for the smaller  
 838 number of study catchments with continuous daily Q time series between 11 and 37 % (with  
 839  $R^2_{CrossVal} = 0.44$  for slope b in RF and  $R^2_{CrossVal} = 0.58$  for  $CV_C/CV_Q$  in PLSR). Especially the  
 840 flashiness index, seasonal ratio of discharge and BFI ranked high with a positive direction of  
 841 influence suggesting that catchments with more equilibrated discharge patterns, i.e. less flashy,  
 842 similar summer and winter discharge ( $Q_{seasR}$  close to 1) and higher base flow, tend to mobilize  
 843 TOC more dynamically with discharge but also show a higher variability in the export patterns  
 844 (**Figure 9b, c**). Our analysis revealed hydrologic variables to be the dominant predictors  
 845 controlling TOC dynamics across the study catchments

846  
 847 **Figure 9.** Mean TOC concentrations against  $twi_{90p}$  (a), slope  $b$  of TOC against seasonality of  
 848 Q ( $Q_{seasR}$ , see Table S2) with colors according to  $twi_{90p}$  from observations (b), and partial  
 849 dependence plot of slope  $b$  TOC from RF model for the variables seasonality and flashiness of Q  
 850 ( $Q_{seasR}$ ,  $Q_{flash}$ ) (c).

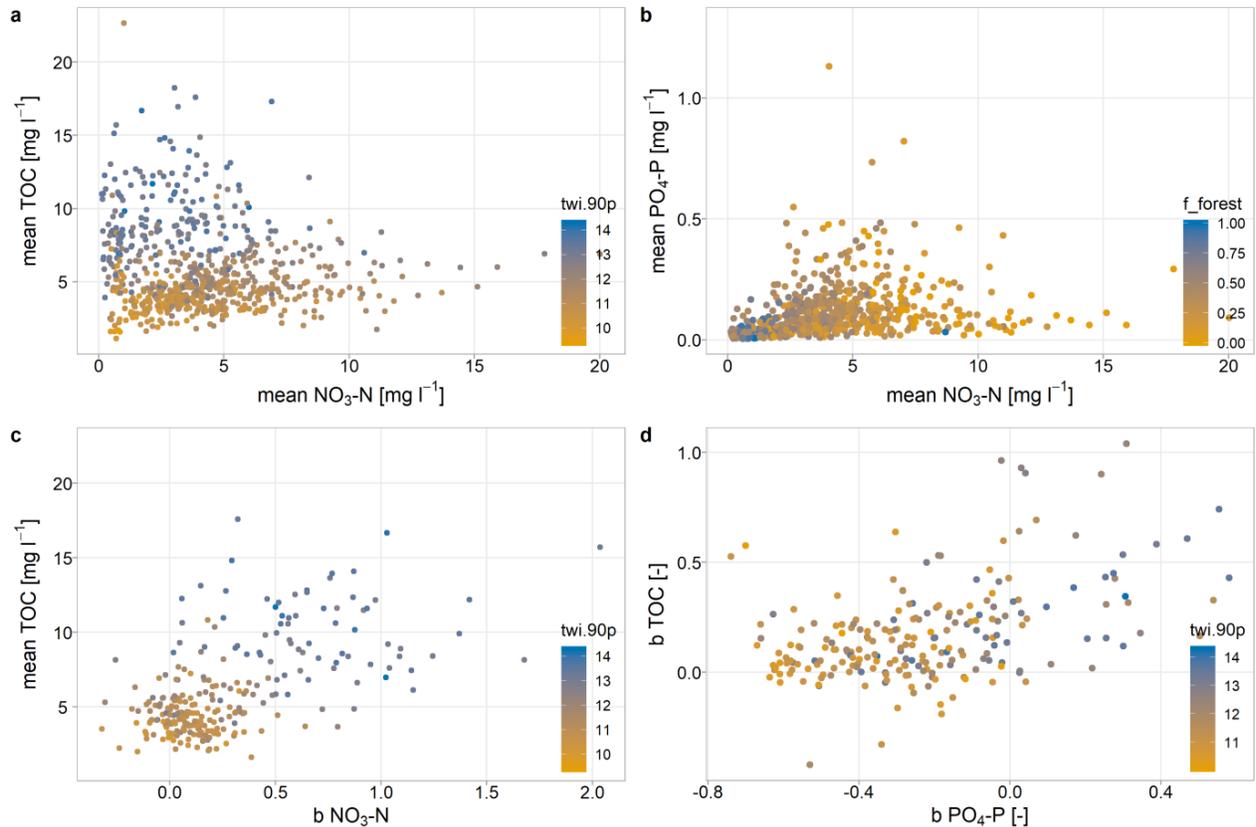

851 However, even with hydrological descriptors, a substantial part of variability in TOC  
 852 export dynamics between the studied catchments remains largely unexplained, which may be  
 853 linked to other drivers of TOC export next to Q, e.g. the temperature (Musolff et al., 2018;  
 854 Winterdahl et al., 2014). Winterdahl et al. (2014) found DOC-Q correlation coefficients across  
 855 Sweden to negatively relate to the mean annual temperature, i.e. DOC export becomes more

856 hydrology driven with lower mean temperatures. This relation could not be observed in our  
857 study, possibly, because the mean annual temperatures across our study catchments were  
858 generally higher (**Figure 1b**) with an average mean temperature of 8.8°C compared to the  
859 maximum mean temperature of 8.6°C in Winterdahl et al. (2014). In this study, we observed that  
860 hydrology strongly controls the export only in study catchments with flatter topography: for  
861 TOC-Q relationships with  $R^2 \geq 0.5$ , the topographic slope was  $< 2.1^\circ$  and  $twi\_90p > 12.2$ , while  
862 the catchments with lower  $R^2$  had a higher mean topographic slope =  $4.3^\circ$  and lower mean  
863  $twi\_90p = 11.7$ . Moreover, antecedent conditions, especially riparian soil temperatures and  
864 moisture and the occurrence of previous events, are known to control DOC production and shape  
865 export patterns in combination with temporally variable hydrological connectivity (Wen et al.,  
866 2020; Werner et al., 2019; Winterdahl et al., 2011). Variable antecedent conditions likely cause  
867 variable source heterogeneity resulting in export variability that cannot be explained by spatio-  
868 temporally aggregated catchment characteristics.

#### 869 4.2. Are Riparian Wetlands Hot Spots of Interacting Nutrient Cycles Across the Wide 870 Range of Catchments?

871 Riparian wetlands are potential hot spots of biogeochemical processes due to high  
872 hydrologic connectivity to the streams and variable redox conditions during dry and wet cycles  
873 with changing water tables (Burt, 2005; McClain et al., 2003). The  $twi\_90p$  is considered a  
874 proxy for the extent of riparian wetlands (Musolff et al., 2018) and was found to be an important  
875 predictor for export metrics of the investigated major nutrients, i.e. mean TOC concentrations  
876 and slope  $b$  of  $NO_3-N$  and  $PO_4-P$ . Thus we discuss the role of possible nutrient interactions  
877 within riparian wetlands.

878 Catchments with a high  $twi\_90p$  tend to have high mean TOC and low mean  $NO_3-N$   
879 concentrations, whereas high  $NO_3-N$  concentrations were mostly observed in catchments with  
880 lower  $twi\_90p$  and lower mean TOC concentrations (**Figure 10a**). The negative relationship  
881 between  $NO_3-N$  and TOC concentrations could be linked to denitrification under anoxic  
882 conditions, the redox reaction with DOC as the electron donor and  $NO_3$  as acceptor, as has been  
883 also observed and discussed in several previous studies (e.g., Dupas et al., 2017; Musolff, Selle,  
884 et al., 2017; Taylor & Townsend, 2010). Thus riparian wetland denitrification could be part of  
885 the increased natural  $NO_3-N$  attenuation in lowlands (see Section 4.1.1.). Mean TOC were also  
886 positively correlated to slope  $b$  of  $NO_3-N$  and both to the  $twi\_90p$  (see **Figure 10c** and Figure 5).  
887 This could indicate that denitrification in riparian wetlands during summer low-flows enhances a  
888 positive  $NO_3-Q$  relationship. This would support the finding that reactivity results in or increases  
889 concentration heterogeneity leading to stronger export patterns. However, as the  $twi\_90p$  is also  
890 correlated to  $het\_v$  ( $r=0.75$ ), which was the dominant control of slope  $b$  of  $NO_3-N$ , the additional  
891 contribution of this interaction within riparian wetland cannot be fully disentangled here.

892

893 **Figure 10.** Interaction between metrics of different nutrients in scatterplots, a) mean TOC  
 894 against mean  $\text{NO}_3\text{-N}$  concentrations, b) mean  $\text{PO}_4\text{-P}$  against mean  $\text{NO}_3\text{-N}$  concentrations, c)  
 895 mean TOC against b  $\text{NO}_3\text{-N}$  and d) slope of  $\text{PO}_4\text{-P}$  against TOC.

896 Additionally,  $\text{NO}_3$  can act as a redox buffer and prevent reductive  $\text{PO}_4$  release from riparian  
 897 wetlands (e.g., Dupas, Gruau, et al., 2015; Gu et al., 2017; Musolff, Selle, et al., 2017), which is  
 898 expected to cause a negative relation between  $\text{NO}_3\text{-N}$  and  $\text{PO}_4\text{-P}$  concentrations in catchments  
 899 with high  $\text{twi}_{90\text{p}}$ . Over the whole range of catchments, the concentrations show a positive  
 900 relation ( $r=0.45$ , see **Figure 5** and **Figure 10b**), which is plausible as both nutrients primarily  
 901 underlie the anthropogenic impact (urban and agricultural, not forest) and could mask interaction  
 902 in riparian wetlands. However, even in catchments without point sources, this negative relation  
 903 was not obvious. Though the interaction between  $\text{NO}_3\text{-N}$  and  $\text{PO}_4\text{-P}$  does not seem to control the  
 904 variability of temporally aggregated concentrations among catchments, it could be relevant on  
 905 other scales, e.g. in long-term trends or seasonal patterns.

906 C-Q slope b of TOC and  $\text{PO}_4\text{-P}$  both relate to high  $\text{twi}_{90\text{p}}$  (**Figure 10d**;  $r=0.28$  for TOC,  
 907  $r=0.46$  for  $\text{PO}_4\text{-P}$ , Figure S4) and correlate positively ( $r=0.41$ , **Figure 5**). This suggests that both  
 908 nutrients could be mobilized in riparian wetlands, which could be linked to dissolution under  
 909 reducing conditions, e.g. due to decreasing  $\text{NO}_3$  concentrations as redox buffers, as discussed by  
 910 Musolff, Selle, et al. (2017).

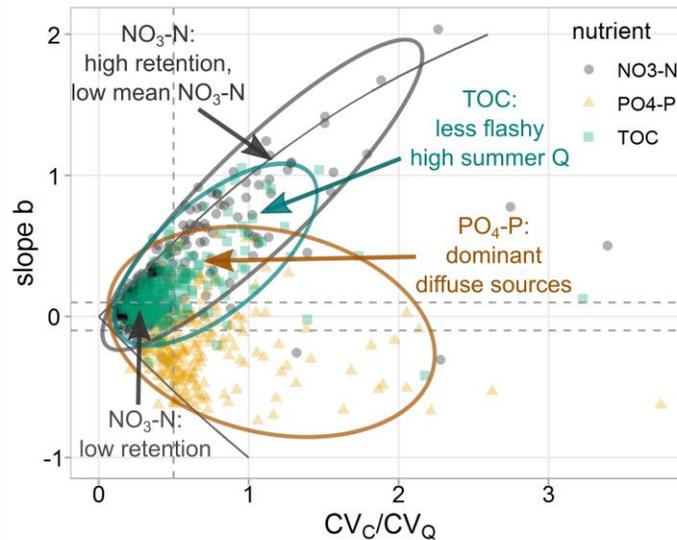

911 Over the wide range of studied catchments, nutrient interactions within riparian wetlands  
 912 possibly affect the variability in catchment responses but they are hard to disentangle from other  
 913 dominant factors such as attenuation in aquifers and mobilization of diffuse sources. Here, we

914 suggest to more rigorously test the role of riparian wetlands in a wide set of catchments allowing  
915 to group for dominant factors.

#### 916 4.3. Archetypal Ranges of Nutrient Export

917 Over the wide range of investigated catchments, solute-specific ranges of the export  
918 patterns and regimes were apparent for each nutrient including gradual transitions within the  
919 ranges (**Figure 3** and **Figure 11**). Accordingly, about 70% of the catchments classify into the  
920 respective dominant groups of each nutrient. Solute-specific prevalence of one pattern and  
921 regime has also been reported previously, e.g. by Minaudo et al. (2019) and Moatar et al. (2017),  
922 though this consistency might be surprising considering the multitude of processes affecting  
923 nutrient cycling, mobilization, transport, and retention. Nevertheless, other studies have also  
924 reported export patterns for the non-dominant classes, e.g. Zarnetske et al. (2018) found negative  
925 C-Q relationships for DOC in about 20% of the 1006 U.S. catchments and Underwood et al.  
926 (2017) found different segmented types of positive and neutral C-Q patterns for dissolved P.  
927 Thompson et al. (2011) showed ranges of export regimes for PO<sub>4</sub>-P and NO<sub>3</sub>-N which include  
928 but also go beyond the respective dominant regime (i.e. chemostatic PO<sub>4</sub>-P and chemodynamic  
929 NO<sub>3</sub>-N export). Altogether, there is evidence that a substance-specific continuum in patterns and  
930 regimes exists which is determined by the bandwidth of solute-specific processes and their  
931 variable hierarchies. The properties of the solute or particulate have a major control on processes  
932 that lead to mobilization, transport and reactivity and thus export of the nutrient, while the  
933 variability within the archetypal ranges is partly linked to catchment characteristics as shown and  
934 addressed by PLSR and RF (see Section 3.4).

935 Dominant controls and characteristics that are linked to the solute-specific ranges have  
936 been discussed in the preceding chapters and are synthesized in **Figure 11**. For NO<sub>3</sub>-N, we found  
937 a strong interaction between anthropogenic and natural controls: while agricultural inputs define  
938 a baseline for mean NO<sub>3</sub>-N concentrations, natural attenuation creates deviations lowering the  
939 mean NO<sub>3</sub>-N. This subsurface denitrification creates vertical concentration heterogeneity  
940 resulting in chemodynamic enrichment patterns. For PO<sub>4</sub>-P, natural P cycling strongly interacts  
941 with anthropogenic sources both from point sources, which link to mean PO<sub>4</sub>-P concentrations,  
942 and diffuse sources, which link to positive C-Q slopes. For TOC, interaction between  
943 anthropogenic and natural controls was not apparent, as the topography strongly controlled mean  
944 concentrations and the spatial variability of export dynamics was partly explained by  
945 hydrological variability. **Figure 11** summarizes these dominating characteristics within specific  
946 parts of the observed ranges.

947

948 **Figure 11.** Archetypal ranges of solute-specific export patterns and regimes with examples of  
 949 typical characteristics of catchments in this area of the nutrient-specific range indicated by  
 950 arrows. Colors of points, ellipse, arrows and typical characteristics are according to the nutrient  
 951 (black - NO<sub>3</sub>-N, orange - PO<sub>4</sub>-P, green - TOC).

#### 952 4.4. Limitations

953 The investigation of mean concentrations, export patterns and regimes and the subsequent  
 954 identification of predictors underlie the assumption of stationarity of catchment-functioning over  
 955 the analysed time period. Even if this is not true in some catchments for some nutrients,  
 956 aggregating over this relatively short period (here 2000-2015) should be acceptable and not  
 957 corrupt the results of the general behaviour we interpreted.

958 Our analysis aggregates low-frequency data over different seasons and climatic  
 959 conditions assuming that general relationships remain apparent and interpretable. Several studies  
 960 have chosen other approaches differentiating low-flow and high-flow conditions by generally  
 961 dividing the C-Q relationships (Moatar et al., 2017; Underwood et al., 2017) or by distinguishing  
 962 event and base flow conditions (Minaudo et al., 2019). Burns et al. (2019) and Duncan et al.  
 963 (2017) discuss that interannual aggregation may lead to more chemostatic C-Q relationships and  
 964 high-frequency sampling may reveal contrasting patterns and processes. Generally, ambivalent  
 965 relationships between C and Q can cause dispersion in C-Q regressions (Bol et al., 2018). We  
 966 acknowledge that our approach could thus enhance scatter in the C-Q relationships and miss  
 967 subscale processes, but the analysis still allowed us to observe spatial and solute-specific patterns  
 968 and interpret the overarching control of catchment characteristics.

969 Further, the spatial aggregation of characteristics over the complete catchments may  
 970 mask drivers at smaller scale. This might be even wanted to reveal hierarchies of processes at  
 971 catchment scale, but if various small-scale processes dominate the response at catchment scale,  
 972 this could also be a reason for a part of the variability in C-Q metrics not explained, as we saw  
 973 for example for PO<sub>4</sub>-P.

974 Here, we note as well that ambiguity in certain predictors can limit clear linking of the  
 975 identified dominant controls to drivers and processes. We tried to reduce this uncertainty by

976 using two composite approaches as model ensemble which allowed us to better discuss  
977 generalities in the dependencies between descriptors and responses, as recommended by  
978 (Schmidt et al., 2020).

979 The cross-validation quantifies the model uncertainty which partly relates to tendencies  
980 of overfitting but also to the subset and variability of samples. The model uncertainty can be  
981 interpreted based on the standard deviation of cross-validated model performances given in  
982 **Figure 6** and on comparisons to model performances of supplemental models with smaller  
983 sample sizes (Table S4-5, S8-10). The uncertainty varies largely between models: the standard  
984 deviations of  $R^2_{\text{CrossVal}}$  were lowest for mean  $\text{NO}_3\text{-N}$  and mean TOC concentrations with 7.3-  
985 9.6% and highest for slope b of TOC in RF with 19.0% (**Figure 6**). The uncertainties are mostly  
986 similar for corresponding PLSR and RF models, though there is a slight tendency for higher  
987 uncertainty in RF models which indicates that RF models could overfit more easily to the train  
988 data. With this they also tend to reach slightly higher performances in cross-validation relating to  
989 the higher flexibility of the model. Therefore, we would like to generally promote that final  
990 model performances should not be judged without considering the model uncertainty in relation  
991 to the set of samples, as the predictability could be easily overestimated. This general variability  
992 also explains small deviations in variable rankings when using a different subset of samples,  
993 especially when descriptors have a similar variable importance.

## 994 **5 Conclusions**

995 To infer drivers of nutrient export over a wide range of catchments, we classified 278  
996 independent catchments across Germany based on C-Q relationships and linked them to  
997 catchment characteristics using PLSR and RF models, while for mean concentrations we used in  
998 total 787 independent catchments.

999 We identified nutrient specific ranges in C-Q relationships with about 70% of catchments  
1000 classifying into the respective dominant C-Q patterns and regimes. Enrichment patterns and  
1001 chemostatic regimes prevailed for  $\text{NO}_3\text{-N}$  and TOC export, whereas dilution and chemodynamic  
1002 export prevailed for  $\text{PO}_4\text{-P}$ . The archetypal ranges of export dynamics demonstrate a solute-  
1003 specific prevalence and possible range of hierarchies among processes. The variability within the  
1004 ranges could partly be explained by distinct anthropogenic and natural catchment characteristics  
1005 though catchments remain complex systems and certain variability remained unexplained.

1006 For  $\text{NO}_3\text{-N}$ , we found that natural attenuation potentially buffers anthropogenic inputs  
1007 reducing mean  $\text{NO}_3\text{-N}$  concentrations and creating concentration heterogeneity within the  
1008 catchment that controls export dynamics. Attenuation was found most dominant in lowland areas  
1009 with deep sedimentary aquifers. According to the observed relationship, enrichment patterns in  
1010 agricultural areas could indicate effective subsurface reactivity. On the other hand, chemostasis  
1011 links to low subsurface attenuation and concentration homogeneity. This means there is a strong  
1012 interaction of anthropogenic and natural drivers, though the latter is not ubiquitous and possibly  
1013 not permanent.

1014 Diffuse and point sources were found relevant for riverine  $\text{PO}_4\text{-P}$  concentrations even if  
1015 the variability in metrics was hard to predict by catchment characteristics. Mean  $\text{PO}_4\text{-P}$  were  
1016 linked to point sources though not strongly, while the variability in  $\text{PO}_4\text{-P}$  dynamics was better  
1017 explained by diffuse sources. Probably, P cycling reshapes  $\text{PO}_4\text{-P}$  responses in the streams  
1018 decoupling them to some degree from their source configuration and land-stream transfer

1019 processes. Stronger P cycling during low-flow could explain that dilution patterns prevail but are  
1020 widely unrelated to point sources, while the fewer enrichment patterns could be linked to diffuse  
1021 sources and P saturation in the top soils. Anthropogenic drivers, including point sources and P  
1022 soil status, proved to be dominant, but responses are strongly reshaped by natural drivers  
1023 hampering predictions at catchment scale.

1024 Natural topographic settings dominantly controlled TOC concentrations: mean TOC were  
1025 strongly linked to the abundance of riparian wetlands as source areas. The hydrological  
1026 descriptors, especially relatively higher summer discharges, increased the explained variability of  
1027 export metrics though the unexplained part remained relatively high suggesting other relevant  
1028 time-variant controls such as antecedent conditions and temperature. At the same time,  
1029 temporally variable conditions and interacting processes can cause dispersion and ambiguity in  
1030 aggregated C-Q relationships and thus reduce overall predictability. We could not find a strong  
1031 influence of anthropogenic sources and drivers for mean TOC concentrations and TOC exports.

1032 Altogether, we found our hypothesis that source heterogeneity widely controls export  
1033 dynamics partly approved. For  $\text{NO}_3\text{-N}$ , not source but vertical concentration heterogeneity  
1034 widely controlled export dynamics, which likely results from subsurface reactivity as the  
1035 dominant process. Strong enrichment patterns occurred in areas with high attenuation, whereas  
1036 without subsurface reactivity and concentration homogeneity, chemostatic export prevailed. For  
1037  $\text{PO}_4\text{-P}$ , the strength of diffuse sources was dominant suggesting that heterogeneity in P soil status  
1038 between top soil and deeper layers drives export patterns. As TOC export patterns remained  
1039 largely unexplained by aggregated characteristics, variable source strength and heterogeneity  
1040 causing intra-annual changes in the C-Q relationships could be the reason. For both  $\text{PO}_4\text{-P}$  and  
1041 TOC, directly hydrologically connected areas are prerequisite for translating vertical source  
1042 heterogeneity to chemodynamic export due to their strong sorption tendency. This connectivity  
1043 can be provided by drained areas creating preferential flow paths or given for locations close to  
1044 the stream such as riparian zones.

1045 As some of the identified controls, especially the anthropogenic, have developed over  
1046 time, the catchment responses may also follow trends on long term. For  $\text{PO}_4\text{-P}$ , for example,  
1047 reductions in point sources and increasing P legacies in agricultural soils might have led to the  
1048 visibility of enrichment patterns by shifting the dominance of processes.  $\text{NO}_3\text{-N}$  could follow  
1049 trajectories from more chemodynamic to more chemostatic export if subsurface reactivity  
1050 decreased over time. With rising temperatures and heavier storm events due to climate change  
1051 (EEA, 2019), nutrient export might change as well as biogeochemical interactions linked to  
1052 temperatures and redox conditions. For example, TOC exports might increase with prolonged  
1053 production times and more variable hydrological connectivity, potentially also enhanced by  
1054 lower  $\text{NO}_3$  redox buffers when depositions and concentrations decrease (Clark et al., 2010). This  
1055 would mean an indirect anthropogenic impact on TOC due to nutrient interactions.

1056 Our findings can support water quality management by giving orientation on how or in  
1057 what range catchments with certain characteristics are expected to respond. If chemostatic  $\text{NO}_3\text{-N}$   
1058 export is apparent, missing or exhausting denitrification capacity of the system might be the  
1059 reason and, in consequence, more efforts for mitigation measures and reduced inputs to protect  
1060 the water quality might be required. Nevertheless, in systems with apparent effective attenuation  
1061 and chemodynamic  $\text{NO}_3\text{-N}$  export, the exported loads might still be high, the natural buffer  
1062 might exhaust in the future or the decrease in concentration be linked to strongly unbalanced  
1063 systems with enormous recovery times. Therefore, controlling inputs seems vital in both cases.

1064 For PO<sub>4</sub>-P, we found that the contribution of diffuse sources can be dominant which indicates  
 1065 that focussing on point sources for P management is not up-to-date, especially because diffuse  
 1066 source mobilization can result in high exported loads affecting downstream water bodies. Water  
 1067 quality modelers can benefit from the presented solute-specific ranges of export dynamics and  
 1068 the identified dominant controls, e.g. the effective reactivity which impacts both concentrations  
 1069 and dynamics of NO<sub>3</sub>-N and biogeochemical processes relating to P cycling.

## 1070 **Author Contributions**

1071 PE conducted the main data preprocessing and analysis, prepared visualizations of results  
 1072 and wrote the manuscript. AM designed and supervised the study. AM, RK, MW, PE mainly set  
 1073 up the data base of water quantity and quality and geoinformation of catchments, the data  
 1074 management, and quality checks. LK calculated vertical heterogeneity across Germany. All  
 1075 authors contributed to writing the manuscript.

## 1076 **Acknowledgments and Data**

1077 We thank the Federal authorities for providing water sample data and all contributors to  
 1078 setting up the used data base, including Thomas Grau, Teresa Nitz and Joni Dehaspe. We thank  
 1079 Martin Bach and Uwe Häußermann for providing the N surplus data. We thank Soohyun Yang  
 1080 and Olaf Büttner for providing the data of small water treatment plants in Germany. We  
 1081 acknowledge the E-OBS dataset from the EU-FP6 project UERRA (<http://www.uerra.eu>) and the  
 1082 Copernicus Climate Change Service, and the data providers in the ECA&D project  
 1083 (<https://eca.knmi.nl>). We further acknowledge several organizations for providing data products  
 1084 used in this study, including the BfG, BGR, SGD, EEA, FAO, IIASA, ISRIC, ISSCAS and JRC.  
 1085 The authors thank for the funding by the Initiative and Networking Fund of the Helmholtz  
 1086 Association through the project Advanced Earth System Modelling Capacity (ESM) ([www.esm-](http://www.esm-project.net)  
 1087 [project.net](http://www.esm-project.net)). The authors declare no conflict of interest.

1088 Datasets for this research are available in these in-text data citation references: Ebeling  
 1089 (2020b) [the repository will be published at acceptance, for revision it is already discoverable],  
 1090 Ebeling (2020a) [published at acceptance, for revision discoverable], Musolff et al. (2020)  
 1091 [original data in institutional repository] and Musolff (2020). Further original datasets used for  
 1092 this research are referenced in **Table 1** and in the text.
