13

14   Key points:

15   • Simulated MCS precipitation and occurrences are substantially underestimated in

16   E3SMv2 over both tropical and CONUS regions.

17   • MCS defined by both cloud shield and surface precipitation provides a more stringent

18   assessment on the model capability in simulating MCSs.

19   • Simulated MCS properties in E3SMv2 are not significantly improved with the new cloud

20   and convection parameterizations developed for E3SMv3.

21

22 **Abstract**

23   Mesoscale convective systems (MCSs) play an important role in modulating the global

24 hydrological cycle, general circulation, and radiative energy budget. In this study, we evaluate

25 MCS simulations in the second version of U.S. Department of Energy (DOE) Energy Exascale

26 Earth System Model (E3SMv2). E3SMv2 atmosphere model (EAMv2) is run at the uniform

27 0.25° horizontal resolution. We track MCSs consistently in the model and observations using the

28 PyFLEXTRKR algorithm, which defines MCS based on both cloud-top brightness temperature

29 (T_b) and surface precipitation. Results from using T_b only to define MCS, commonly used in

30 previous studies, are also discussed. Furthermore, sensitivity experiments are performed to

31 examine the impact of new cloud and convection parameterizations developed for EAMv3 on

32 simulated MCSs.

33   Our results show that EAMv2 simulated MCS precipitation is largely underestimated in

34 the tropics and contiguous United States. This is mainly attributed to the underestimated

35 precipitation intensity in EAMv2. In contrast, the simulated MCS frequency becomes more

36 comparable to observations if MCSs are defined only based on cloud-top T_b. The T_b-based MCS

37 tracking method, however, includes many cloud systems with very weak precipitation which

38 conflicts with the MCS definition. This result illustrates the importance of accounting for

39 precipitation in evaluating simulated MCSs. We also find that the new physics parameterizations

40 help increase the relative contribution of convective precipitation to total precipitation in the

41 tropics, but the simulated MCS properties are overall not significantly improved. This suggests

42 that simulating MCSs will remain a challenge for the next version of E3SM.

43

44

Plain Language Summary

45

46   Mesoscale convective systems (MCSs) are one of the largest forms of deep convective

47 storms, which play an important role in the earth system. It is imperative for global climate

48 models to reasonably simulate the MCS properties. This study aims to evaluate the simulated

49 MCS properties in the second version of U.S. Department of Energy (DOE) Energy Exascale

50 Earth System Model (E3SMv2). We utilized two different approaches to define and track MCSs

51 in the model and observations for consistent comparisons. Our results show that the E3SMv2

52 model underestimates MCS precipitation in the tropics and contiguous United States regions.

53 The too weak precipitation intensity is the primary reason for this MCS precipitation bias. The

54 simulated MCS number becomes more comparable to the observations when precipitation

55 features are not included in the MCS definition. However, many cloud systems with precipitation

56 characteristics not associated with MCSs are falsely included. Therefore, this comparison

57 illustrates the importance of accounting for precipitation features in evaluating simulated MCSs.

58 In addition, by examining the impact of new physics parameterizations that are developed for the

59 next generation of E3SM model on the MCS simulation, we find simulating MCSs will remain a

60 challenge for the next version of E3SM model.

61

62   **1. Introduction**

63   Mesoscale convective systems (MCSs) are the largest form of cumulonimbus cloud

64   aggregates that cover a horizontal scale of hundreds of kilometers with lifetimes that can last

65   more than 24 hours (Houze et al., 2004, 2018). Observations show that MCSs are ubiquitous

66   over the tropics (Nesbitt et al., 2006; Yuan & Houze, 2010) and contribute to more than 50% of

67   total precipitation in the tropical region (Nesbitt et al., 2006; Feng et al., 2021a), as well as over

68   the Great Plains east of the Rocky Mountains in the contiguous United States (CONUS) region

69   (Feng et al., 2016; Haberlie & Ashley, 2019). MCSs contain both active convective towers and

70   extensive stratiform clouds, which differentiates them from ordinary convective storms (Houze

71   et al., 2018). The presence of robust stratiform anvil clouds and precipitation in MCSs produce

72   top-heavy heating profiles that impact global circulations (Schumacher et al., 2004) and feedback

73   on the evolution of MCS lifecycle (Yang et al., 2017, 2023). Using long-term observations over

74   the past decades, the frequency and intensity of springtime MCSs are found to increase in the

75   central U.S., which is associated with a strengthening of the southerly low-level jet and

76   associated moisture transport in the Central and Northern Great Plains (Feng et al., 2016; You &

77   Deng, 2023). Such an increase in MCS frequency and intensity also suggests a potential future

78   increase in extreme rainfall occurrence in the warming climate (Prein et al., 2017). Therefore,

79   MCS plays an important role in the global hydrological cycle, large-scale state environments,

80   and global energy budget.

81   To better understand the changes of MCSs in the future climate, it is imperative to

82   accurately represent their key characteristics in regional and global climate models. However,

83   there are large uncertainties in current numerical models with respect to the representation of

84   essential cloud processes associated with MCS formation and development (e.g., Fan et al.,

85   2017; Moncrieff, 2019). This is particularly true for conventional general circulation models

86   (GCMs) with a coarser horizontal resolution and convective parameterizations to simulate the

87   multiscale interactions in MCSs (Feng et al., 2021b; Hsu et al., 2023). For GCMs that participate

88   in the Coupled Model Intercomparison Project Phase 5 (CMIP5), most models simulate a severe

89   underestimation of summertime precipitation over the central U.S. (Lin et al., 2017; Mueller &

90   Seneviratne, 2014), which is a longstanding issue that is believed to be associated with the

91   failure to capture strong precipitation events produced by MCSs (Klein et al., 2006; Van

92   Weverberg et al., 2018; Xie et al., 2019; Zheng et al., 2019). However, low-resolution GCMs are

93   computationally efficient tools currently used in century-long climate projections and to

94   understand changes in global convection and cloud properties under future climate scenarios.

95   Therefore, it remains important to understand and improve the representation of convection and

96   MCS processes in GCMs with coarser horizontal resolutions.

97   Previous studies show that GCMs can simulate MCSs that are comparable to

98   observations at ~50 km horizontal resolution on the global scale. Dong et al. (2021) compared

99   the characteristics of tropical MCSs using high resolution (~50 km) Geophysical Fluid Dynamics

100   Laboratory (GFDL) AM4 model (C192AM4, Zhao, 2020) with a comprehensive long-term

101   observational dataset. They showed that the spatial distribution of MCSs as well as the

102   seasonality and interannual variability of MCS frequency over different land and oceanic regions

103   are reasonably simulated. Dong et al. (2023) additionally suggested that the spatial distribution

104   and seasonality of genesis frequency of MCSs during spring to early summer are also broadly in

105   agreement with observations over the central U.S. However, the identified MCSs in these two

106   studies are purely based on the cloud-top brightness temperature (T_b) data (Huang et al., 2018).

107   More recently, a new MCS tracking algorithm has been developed that uses both T_b and surface

108   precipitation characteristics (Feng et al., 2023). By comparing the difference in tracked MCSs

109   using the two approaches on the global scale, Feng et al. (2023) found that the T_b-only tracking

110   method produces more MCS occurrences in the midlatitudes compared with the T_b and

111   precipitation method. The false MCS identification by the T_b-only method is related to cloud

112   systems that have long lifetime and cover a large area but generate very low surface precipitation

113   intensity. These cloud systems are more likely to mainly contain stratiform-type precipitation

114   associated with synoptic systems which is inconsistent with the typical MCS precipitation

115   characteristics. Therefore, combining both T_b and precipitation features to track MCS should be

116   more accurate in terms of capturing the essential MCS characteristics.

117   This more advanced MCS tracking algorithm has been used in Wang et al. (2021) to

118   evaluate the simulation of MCS in the Department of Energy's Energy Exascale Earth System

119   Model version 1 (E3SMv1) (Golaz et al., 2019). Wang et al. (2021) found that the E3SM

120   atmosphere model (EAMv1) (Rasch et al., 2019; Xie et al., 2018) can reasonably capture the

121   observed spatial pattern of spring season total precipitation in the CONUS region with a regional

122   refined model (RRM) setup featuring 0.25° model resolution over the CONUS (Tang et al.,

123   2019). However, the model greatly underestimates heavy precipitation over the southern states in

124   the CONUS, and thus underestimates the MCS precipitation and MCS occurrences compared to

125   the observations. Similar underestimation in MCS precipitation was found in the central U.S. and

126   Indo-Pacific region when evaluating the global 0.25° E3SMv1 results (Xie et al., 2020). In

127   addition, the underestimation of MCS precipitation still exists over the CONUS in summertime,

128   even though a cloud resolving model is coupled in E3SMv1 using the super-parameterization

129   approach (Lin et al., 2022), which suggests the deficiencies in model capability to simulate MCS

130   events in E3SMv1.

131   The second version of E3SM along with its North American RRM version has recently

132   been released (Golaz et al., 2022; Tang et al., 2023). E3SMv2 includes minor improvements in

133   its physics parameterizations but with significantly retuned cloud and convection related

134   parameters. For its updated physical parameterizations, a new convective trigger described in Xie

135   et al. (2019) is implemented in E3SMv2 to improve its simulation of precipitation and its diurnal

136   cycle (Golaz et al., 2022; Tang et al., 2022; Tao et al., 2022, 2023). The new trigger and the re-

137   adjusted model parameters have also led to considerable improvements in the cloud simulation

138   compared to E3SMv1 (M. Zhang et al., 2022, 2023; Y. Zhang et al., 2023; Qin et al., 2023). In

139   this study, we perform a comprehensive evaluation of E3SMv2's capability to simulate MCS by

140   using the MCS tracking algorithm developed in Feng et al. (2023). To make the model resolution

141   more relevant to the horizontal scales of MCS, the global 0.25° horizontal resolution is used in

142   this study for a global MCS evaluation. In addition, a new set of cloud and convection

143   parameterizations that are developed for the third version of E3SM (E3SMv3) is also tested in

144   this study to examine their impacts on the simulated MCS. To demonstrate the impact of

145   different MCS tracking methods on the model evaluation, we apply both the T_b-only tracking

146   and combined T_b and surface precipitation tracking in our evaluations.

147   The paper is organized as below. Section 2 introduces the default model physics

148   parameterizations in E3SMv2 and the new convection and cloud microphysics parameterizations

149   that are developed for E3SMv3. Observational dataset used for the model evaluation and the

150   MCS tracking method are also described in this section. Section 3 discusses the E3SMv2 model

151   evaluation results, the impact of different MCS tracking methods on the global scale and over the

152   CONUS region, and the impact of new physics parameterizations on the MCS simulation. The

153   summary and discussion are provided in section 4.

154

2. EAMv2, numerical experiments, observations, and MCS tracking

2.1. EAMv2 model

157   EAMv2 features a few notable changes in the atmospheric physics and significantly

158   recalibrated tuning parameters compared to EAMv1 (Golaz et al., 2022). Specifically, the

159   dCAPE_ULL convective trigger described in Xie et al. (2019) was implemented in the deep

160   convection scheme (Zhang & McFarlane, 1995, ZM hereafter) in EAMv2 to improve the

161   simulated precipitation and its diurnal cycle. The new convective trigger combines the dynamical

162   Convective Available Potential Energy (CAPE) (dCAPE) trigger developed in Xie and Zhang

163   (2000) to prevent CAPE from being released simultaneously after its generation and the

164   Unrestricted air parcel Launch Level (ULL) method described in Wang et al. (2015) to allow

165   convective instability to be detected above the boundary layer for elevated nocturnal

166   convections. In addition, a new linearized ozone scheme is used for stratospheric ozone (Tang et

167   al., 2021). The treatments of other physical processes are the same as in EAMv1, which include

168   the Cloud Layers Unified by Binormals (CLUBB, Golaz et al., 2002; Larson, 2017)

169   parameterization for shallow convection, cloud macrophysics, and boundary layer turbulence;

170   the second version of Morrison and Gettelman (MG2, Gettelman & Morrison, 2015; Gettelman

171   et al., 2015) cloud microphysics; the four-mode Modal Aerosol Model (MAM4, Liu et al., 2016;

172   Wang et al., 2020), and the gravity wave parameterization following Richter et al. (2010) with

173   updated treatments (Beres et al., 2004; Richter et al., 2019). In addition, significant re-

174   adjustments were made to a number of parameters used in cloud microphysics, CLUBB, and

175   deep convection schemes to improve the cloud and precipitation simulation and cloud radiative

176   forcing (Ma et al., 2022). In this study, we run EAMv2 at 0.25° horizontal resolution globally

177   with a 900 second time step. Note that this 0.25° horizontal resolution model configuration is not

178   officially supported. However, the cloud and precipitation climatology remains reasonable in our

179   model validation compared with the standard low resolution version of E3SMv2. Thus, it is

180   suitable for this study.

181

182   **2.2. Numerical experiments**

183   **2.2.1. Simulation setup**

184   In this study, EAMv2 is run at a global uniform 0.25° horizontal resolution from 2004 to

185   2009. The sea surface temperature and sea ice are prescribed by weekly observational data from

186   the National Oceanic and Atmospheric Administration (NOAA) Optimum Interpolation Sea

187   Surface Temperature version 2 (OISST v2) product (Huang et al., 2021). The model simulation

188   results between 2005 and 2009 are used for the MCS evaluation with the first-year results

189   discarded for model spin-up. Hourly outputs of global surface precipitation flux and outgoing

190   longwave radiation are saved and used for the MCS tracking. The MCS tracking approach is

191   introduced in Section 2.4.

192

193   **2.2.2. Sensitivity tests with cloud and convection physical parameterizations**

194   To examine the impact of model physics on the simulation of MCS, we perform a set of

195   sensitivity experiments with different cloud and convection parameterizations developed for the

196   next version of E3SM atmosphere model (i.e., EAMv3). One of the major developments is the

197   use of predicted particle properties (P3) cloud microphysics scheme (Milbrandt & Morrison,

198   2016; Milbrandt et al., 2021; Wang et al., 2021) to replace the MG2 stratiform cloud

199   microphysics that was used in EAMv1 and EAMv2. Convective cloud parameterizations

200   received several significant updates during the model development. First, the two-moment

201   convective cloud microphysics parameterization (Song & Zhang, 2011; Song et al., 2012) is

202   implemented to more physically represent the evolution of convective cloud hydrometeors and

203   their interactions with large-scale stratiform clouds and aerosols. Second, the multiscale coherent

204   structure parameterization (MCSP, Chen et al., 2021; Moncrieff et al., 2017; Moncrieff, 2019) is

205   introduced to simulate the physical and dynamical effects of organized convection that are

206   currently missed in EAMv2. Third, a cloud base mass flux adjustment described in Song et al.

207   (2023) is incorporated into the ZM scheme to improve the coupling of deep convection and its

208   associated large-scale environment. In this study, we perform four sensitivity experiments to

209   examine their individual impacts from all four new features. The control run with the default

210   EAMv2 and the sensitivity tests are summarized in Table 1. Below, we provide more details on

211   the tested new parameterizations.

212

213   **1) P3 microphysics**

214   P3 is a new bulk cloud microphysics scheme that represents the evolution of physical

215   properties of various hydrometeors in space and time (Milbrandt & Morrison, 2016; Milbrandt et

216   al., 2021). Unlike the MG2 cloud microphysics scheme used in the default EAMv2 model which

217   artificially defines separate hydrometeor categories for different ice species, P3 represents the

218   evolution of ice particle properties from ice crystals to snow and rimed particles (e.g., graupel)

219   by prognosing rimed mass and volume. This method avoids the impact of artificial separation of

220   ice species on the simulation of ice particle microphysical processes, thus improving the

221   representation of physical evolution of ice particles in the model. Considering rimed particles,

222   which is important for MCS precipitation, is another advantage of P3 compared with MG2, in

223   which only cloud ice and snow are considered. The current P3 implemented in E3SM is two-

224   moment, which prognoses the total ice mass mixing ratio and ice number concentration with the

225   predicted ice mass from riming growth and the rimed volume to track the particle growth

226   processes (Wang et al., 2021). Note that the single ice category is used in E3SM, meaning that

227   there is only one single type of ice particle predicted at a given time in one model grid. For liquid

228   phase hydrometeors, a two-moment bulk scheme is used to prognose the mass mixing ratio and

229   number concentration of cloud droplet and rain drop in their evolution. By comparing P3 with

230   the default MG2 cloud microphysics EAMv1 RRM simulation, Wang et al. (2021) showed that

231   P3 microphysics greatly improves the simulation of precipitation statistics over the CONUS

232   region. The higher hourly rain rate simulated by P3 results in 20% more MCS occurrence and

233   stronger total MCS precipitation than MG2, which agrees better with the observations.

234

235   **2) Convective cloud microphysics**

236   The convective cloud microphysics developed by Song and Zhang (2011) prognoses the

237   mass mixing ratio and number concentration of cloud droplet, cloud ice, rain, and snow in the

238   ZM parameterization. Cloud microphysical processes including autoconversion, collection

239   between hydrometeor species, self-collection, freezing, ice nucleation, droplet activation, and

240   sedimentation are represented to simulate the evolution and interaction between different

241   hydrometeor species. Previous studies showed that this convective cloud microphysics scheme

242   enables a more accurate convection and precipitation simulation (Song et al., 2012). The

243   interactions between convective clouds and aerosols and large-scale clouds are also better

244   represented in the model, in particular, the aerosol impacts on convective clouds can be

245   examined in GCMs with this new convective cloud microphysics.

246

3) MCSP

248 To account for the important mesoscale heating associated with convective organization,

249 Chen et al. (2021) implemented the MCSP parameterization (Moncrieff et al., 2017; Moncrieff,

250 2019) in E3SM. The MCSP simulates the heating effects of the slantwise overturning structure

251 typically organized by MCSs. The heating component of MCSP contains a temperature tendency

252 of multiscale convective systems that is added to the temperature tendency simulated by the

253 existing ZM parameterization. The heating profile is represented as a top-heavy second

254 baroclinic normal mode and its amplitude is a function of the vertically averaged convective

255 heating induced by the convective parameterization. Chen et al. (2021) showed that the MCSP

256 improves the representation of the Madden-Julian Oscillation (MJO) and reduces the

257 precipitation biases over the tropical Pacific region in E3SMv1.

258

4) Cloud base mass flux adjustment

260 To represent the dynamical effects of large-scale vertical motion on the convection

261 development, model simulated cloud base mass flux adjustment is introduced in EAMv2 (Song

262 et al., 2023). The cloud base mass flux is adjusted by subtracting the grid-scale pressure vertical

263 velocity at the PBL top from the cloud base mass flux determined in the CAPE closure in the ZM

264 scheme. In this case, the moisture transported through the PBL top by large-scale vertical motion

265 becomes fully available for the convective cloud development. As simulated convection is

266 directly modulated by the large-scale dynamical circulation, such a cloud base mass flux

267 adjustment enables the ZM scheme to better represent convection generation in the low-CAPE

268 environment. Song et al. (2023) indicated that the cloud base mass flux adjustment substantially

269 improves the climate variability across multiple scales, from the precipitation diurnal cycle to the

270 MJO.

271

272 **2.3. Observations**

273   The observational dataset used to evaluate global MCS properties are the NASA Global

274 Merged IR V1 infrared T_b product (Janowiak et al., 2017) and the Global Precipitation

275 Measurement (GPM) Integrated Multi-satelliteE Retrievals (IMERG) V06B precipitation data

276 (Huffman et al., 2019a, 2019b, 2019c). The global T_b data are derived from geostationary

277 satellites that cover the region between 60°S-60°N latitudes at 4 km pixel resolution. The

278 IMERG precipitation is estimated from various precipitation-relevant satellite passive

279 microwave sensors at 10 km horizontal resolution. The hourly global T_b and precipitation

280 satellite observational datasets are regridded to 0.25° (~25 km) horizontal resolution to match the

281 model grid spacing.

282   Over the CONUS region, in addition to the coverage of satellite T_b and precipitation

283 observations, radar reflectivity from the National Weather Service Next-Generation Radar

284 (NEXRAD) and the Stage IV multi-sensor precipitation datasets are also available. Following

285 Feng et al. (2019), the NEXRAD radar reflectivity data, the Stage IV precipitation estimates, and

286 the Merged IR V1 infrared T_b product are combined to derive the MCS tracking product (Feng,

287 2019). Note that the original horizontal resolution of this MCS product over the CONUS is 4 km.

288 Same as the global satellite MCS data, this radar and rain gauge observation dataset is also

289 regridded to 25 km, consistent with the model simulations. The MCS products from 2005 to

290 2009 are used to evaluate EAMv2 model simulations. Table 2 summarizes the observational

291 datasets used for the MCS tracking in this study.

292

2.4. MCS tracking method

293

294   This study uses the PyFLEXTRKR (Python FLEXible object TRacKeR) software

295   package (Feng et al., 2022) to identify and track the time evolution and spatial distribution of

296   MCS and calculate the statistics of MCS properties in the observation and EAMv2 model

297   simulations. PyFLEXTRKR (Feng et al., 2023) is a flexible atmospheric feature tracking

298   software package with specific capabilities to track MCS features based on T_b and precipitation

299   characteristics. Note that the EAMv2 model outputs the outgoing longwave radiation (OLR)

300   instead of T_b. To consistently define simulated MCS as the observations, OLR is converted to T_b

301   in PyFLEXTRKR following the empirical method by Yang and Slingo (2001).

302   The detailed workflow for tracking MCSs is described in Feng et al. (2023). The first step

303   of MCS tracking is to identify the cold cloud system (CCS) associated with deep convective

304   events in the observation and model simulations. The CCS is detected by iteratively growing a

305   cold cloud core with $T_b < 225$ K outwards to 241 K. After each CCS segments are defined, if the

306   CCS from two consecutive time steps (1 hour apart) overlaps for more than 50% of their area,

307   the CCS pairs are linked to track their temporal evolution. Along the CCS temporal evolution, if

308   the CCS area exceeds 4 x 10^4 km^2 and the duration of CCS is longer than 6 hours, the track is

309   then considered as MCS. This T_b based MCS definition is similar to that used in Dong et al.

310   (2021, 2023) for the GFDL C192AM4 model evaluation, although their MCS tracking method

311   (Huang et al., 2018) was based on the thresholds of T_b and a minimum area coverage. In

312   additional to the T_b defined MCS, PyFLEXTRKR has an option to further consider surface

313   precipitation characteristics as an additional criterion for defining MCSs. For the MCS tracking

314   with precipitation, precipitation feature (PF) statistics are calculated over the regions where

315   precipitation rate is greater than 0.5 mm hr^{-1} underneath the CCS. Calculated PF statistics include

316   PF centroids, area, major axis length, mean and maximum rain rate, rain rate skewness, and total

317   and heavy rain volume. Three PF parameters are used to identify and track robust MCSs, which

318   are the PF area, PF mean rain rate, and PF rain rate skewness. If these three PF parameters of a

319   CCS track exceed their corresponding thresholds, that track is defined as a robust MCS. The

320   corresponding tunable threshold values follow a linear function of duration when the largest PF

321   major axis length is greater than 100 km. In the following discussion, if not explicitly mentioned,

322   we refer "MCS" as the MCSs detected by the combined method using both T_b and surface

323   precipitation. Table A1 lists all the parameters used in the MCS tracking and sampling. Note that

324   these tunable parameters are sensitive to the data resolution, particularly for the thresholds

325   related to precipitation. We adjusted these thresholds based on the previous work that matched

326   MCS tracking statistics between coarse resolution (0.25°-0.5°) and high resolution (0.04°)

327   datasets over the CONUS region (Feng et al., 2021b). More details of the tracking method can be

328   found in Feng et al. (2023).

329   In this study, our evaluation primarily focuses on the robust MCSs defined with both T_b

330   and precipitation. MCSs defined by the T_b-only method are also examined to demonstrate the

331   impact of different MCS tracking approaches on evaluating the model capability in capturing

332   MCS properties, which helps explain the differences between the current study and previous

333   literatures relevant to the MCS evaluation in GCMs (e.g., Dong et al., 2021, 2023; Hsu et al.

334   2023).

335

336   **3. Results**

337   **3.1. MCS simulated in EAMv2**

3.1.1. Global MCS

338

339   We evaluate the global MCS properties simulated with the default EAMv2 model physics

340   against observations. Figure 1 compares the global spatial distribution of annual mean total and

341   MCS precipitation amount between 60°S and 60°N. For total precipitation, the default EAMv2

342   model reasonably simulates the large precipitation amount along the intertropical convergence

343   zone (ITCZ) region. Precipitation in the South Pacific convergence zone (SPCZ) is also

344   comparable to the IMERG observation. However, simulated total precipitation in the tropical

345   Indian Ocean and the Maritime Continent region is underestimated by ~30% in EAMv2 (Figure

346   2a). Over the Amazon region, the model also slightly underestimates total precipitation

347   compared to the observation, but strong precipitation peaks are found in the coastal region of

348   Colombia near the equatorial eastern Pacific Ocean. In terms of the MCS precipitation (Figures

349   1c and 1d), observations show that MCSs greatly contribute to the total precipitation in the

350   tropics. Observed MCS precipitation well co-locates with the spatial patterns of total

351   precipitation occurrences, where the ITCZ, SPCZ, tropical Indian Ocean, and Maritime

352   Continent regions have the largest MCS precipitation amount. In EAMv2, it is encouraging that

353   the spatial distribution of simulated MCS precipitation is overall reasonably simulated. For

354   example, simulated MCSs are dominant over the ITCZ, SPCZ, and tropical Indian Ocean.

355   However, the simulated MCS precipitation amount is underestimated by more than 60%

356   compared to the observation (Figure 2b). The underestimation is most substantial over the

357   Maritime Continent and tropical Indian Ocean, while the underestimation is also noticeable over

358   the tropical lands (e.g., Africa and Amazon) and midlatitude storm tracks.

359   We note that earlier literatures stated that GCMs at 50 km horizontal resolution can

360   reasonably capture observed MCSs in the tropics (Dong et al., 2021), which seems to be

361   inconsistent with our current analysis. One possible reason for this is a different MCS tracking

362   method used in Dong et al. (2021), which only used T_b. To understand the impact of different

363   MCS tracking methods on the GCM evaluation, we additionally show the MCS precipitation

364   defined only using T_b in both observation and EAMv2 (Figures 1e and 1f) and the MCS

365   precipitation amount difference between two definitions (Figures 2d and 2e). Compared with the

366   MCS precipitation defined with T_b and precipitation, Figure 2c indicates that the low bias of

367   MCS precipitation is slightly alleviated using the T_b-only tracking method. The larger MCS

368   precipitation from MCSs defined with T_b are more noticeable over the tropical land areas (e.g.,

369   Africa, Amazon, and Maritime Continent) and to a lesser degree over midlatitude storm tracks

370   (Figure 2e). On the other hand, the precipitation difference between two MCS tracking methods

371   is substantially smaller for the IMERG observation, particularly in the tropics. The small impact

372   from MCS tracking method on the observed MCS precipitation suggests that the mesoscale

373   cloud structures associated with observed MCSs nearly always contain heavy precipitation

374   features. However, this is not the case for the model. This comparison suggests that using the T_b-

375   only method could possibly overestimate the model's capability in simulating MCSs.

376   The contribution of MCS precipitation to total precipitation is evaluated in Figure 3 by

377   examining the MCS precipitation fraction between EAMv2 and the IMERG data. In the tropics,

378   the observed annual mean MCS precipitation is found to contribute to up to 90% of total

379   precipitation, and the largest MCS precipitation contribution is found in the Indo-Pacific region.

380   This is consistent with previous studies (Nesbitt et al. 2006; Feng et al., 2021a). In contrast, the

381   default EAMv2 simulated MCS precipitation fraction is significantly lower than observed

382   (Figure 3e). The simulated MCS precipitation fraction rarely reaches 80%. Using the T_b-only

383   tracking method, the MCS precipitation fraction increases largely in the tropical land (Africa and

384   Amazon) and midlatitude storm tracks compared to MCSs defined with combined T_b and

385   precipitation in EAMv2 (Figure 3f). However, the simulated MCS precipitation fraction remains

386   underestimated compared to observations using the T_b-only method.

387   Figure 4 compares the MCS precipitation frequency between EAMv2 and the

388   observations. The MCS precipitation frequency is calculated as the number of hours MCS

389   precipitation occurred (rain rate > 0.5 mm h^{-1}) divided by total number of hours in the five years

390   period. In the observation, the large MCS precipitation frequency appears in the same regions

391   where observed MCS precipitation is large. There are also relatively high MCS precipitation

392   occurrences in the midlatitude storm track region in the northern hemisphere. Compared to the

393   observations, the EAMv2 simulated MCS frequency is largely underestimated over the tropical

394   Indo-Pacific warm pools and midlatitude regions (Figure 4e). This is consistent with the

395   underestimated MCS precipitation in Figure 2b. However, over the central Pacific Ocean, the

396   simulated MCS occurrence becomes comparable to the observations, while over the tropical

397   eastern Pacific Ocean, EAMv2 shows higher MCS frequency even though its MCS precipitation

398   is slightly underestimated. The overestimated frequency of occurrence could imply either the

399   simulated MCSs occur too frequently, or they are overly long-lived. In addition, simulated MCS

400   precipitation frequency and precipitation amount are both overestimated over the tropical Andes

401   and east African highlands.

402   To provide more insights on the MCS occurrence, Figure 5 shows the annual mean MCS

403   number in both the model and observation. The MCS number is counted as the number of unique

404   latitude/longitude pairs of each MCS track within a $5° \times 10°$ latitude/longitude grid. The

405   difference between MCS number and MCS frequency (Figure 4) is that the impact of MCS

406   lifetime and area footprint is excluded from the MCS counts in Figure 5. For example, if an MCS

407   takes a few hours to slowly pass one grid, the MCS number in this grid is counted once but the

408   occurrence of frequency of MCS is the total number of hours this MCS takes to move over the

409   grid. In Figure 5, the location of large observed MCS number is overall consistent with those

410   regions having large MCS frequency and MCS precipitation amount. However, the number of

411   MCSs defined using both T_b and precipitation in EAMv2 is largely underestimated globally

412   except over the central Pacific Ocean and SPCZ region (Figure 5e). Such an underestimation of

413   MCS number suggests that the overestimated MCS precipitation frequency in the tropical eastern

414   Pacific Ocean (Figure 4e) may be caused by the overly long-lived and/or larger MCSs. Further

415   analysis shows that the underestimated MCS number is the result of underestimated MCS

416   genesis in the tropics (not shown).

417   Consistent with MCS precipitation amount, the T_b-only MCS tracking method results in

418   a substantial increase in MCS precipitation frequency and MCS number compared to MCSs

419   tracked using the combined method in EAMv2, particularly over Congo and Amazon (Figures 4f

420   and 5f). Additional increase in the simulated MCS number in the Maritime Continent, tropical

421   Indian Ocean, and midlatitude continents are also found, leading to a more comparable MCS

422   number spatial distribution to the observations. Note that such an increase in MCS frequency and

423   number is less noticeable for the observations (not shown). Dong et al. (2021) also found that

424   MCS defined using only T_b well produces the resemblance of observed tropical MCS number in

425   the GFDL C192AM4 model, where they concluded that GCM is capable of simulating MCS

426   characteristics at 50 km horizontal resolution. However, our current analysis shows that if

427   surface precipitation is included in the MCS tracking to sample more robust MCSs, it is still

428   challenging for EAMv2 to simulate MCSs at 25 km horizontal grid spacing.

429   To further evaluate the MCS characteristics in EAMv2, Figure 6 compares the

430   probability density function (PDF) of simulated and observed MCS properties over the Indo-

431   Pacific region to understand the reasons for the biased MCS precipitation in EAMv2 and the

432   impact of different MCS definitions on MCS evaluation. The choice of Indo-Pacific region is

433   because of (1) the largely underestimated MCS precipitation amount in simulated MCSs; (2) the

434   substantial increase in MCS number between two tracking methods in EAMv2, while the

435   IMERG observation presents negligible difference.

436   Figure 6 shows that most of the simulated MCS properties differ substantially from the

437   observation for MCSs tracked using combined T_b and precipitation, with the exceptions in the

438   maximum CCS area and maximum PF area. Compared to the observation, EAMv2 simulated

439   MCSs tend to have longer CCS lifetime, warmer minimum cloud-top T_b (i.e., lower convective

440   cloud-top height), and weaker mean rain rate within the PF area. Although the model

441   overestimates the probabilities of total rain volume and heavy rain volume between 10^6 and 10^7

442   kg, the heavy rain ratio (i.e., heavy rain volume divided by total rain volume) in EAMv2 peaks at

443   a lower value (~50%) than the observation (~75%). The lower heavy rain ratio is probably

444   associated with the underestimated convection strength, which is indicated by the large

445   occurrences of warm cloud-top T_b in the model (minimum T_b warmer than 205 K). These warm

446   T_b occurrences suggest the simulated MCS in EAMv2 is less penetrative compared to the

447   observed MCS, implying the issue in representing MCS development in the model physical

448   parameterizations. Moreover, by comparing the PDFs of CCS area and PF area to the PDFs of

449   PF features, it is likely that the weaker precipitation intensity, rather than the areas of convective

450   clouds or surface precipitation, explain the underestimated MCS number (Figure 5) and their

451   associated precipitation (Figures 1-2). This speculation is supported by the fact that in the eastern

452   Pacific Ocean, where the default EAMv2 better simulates MCS precipitation amount, the PDF of

453   heavy rain ratio tends to peak at ~78% which matches the IMERG observation (~80%) more

454   than any other examined locations (not shown).

455   For MCSs defined with two different methods, it is shown that the PDFs of MCS

456   properties are nearly identical in the observation over the Indo-Pacific region. The comparable

457   PDFs between MCSs defined with T_b and combined T_b and precipitation are also found in other

458   regions (i.e., eastern Pacific Ocean, Africa and Amazon tropical lands, not shown). In other

459   words, the MCS precipitation features are nearly always generated in these mesoscale cloud

460   structures, especially over the tropics. Such a feature indicates the robustness of observed MCS

461   characteristics using the cloud-top T_b tracking. However, the differences in MCS properties

462   between the two MCS definitions are substantially larger in EAMv2. The largest discrepancies

463   are found in the lifetime minimum T_b and heavy rain volume ratio. For example, while the

464   minimum T_b of MCSs defined using combined T_b and precipitation peaks at ~198 K, which is

465   comparable to the observation, the largest occurrence of minimum T_b for MCSs defined with T_b

466   locates at ~215 K, suggesting cloud clusters with much weaker convective strength are included.

467   Meanwhile, the largest occurrence for heavy rain volume ratio locates below 5% for MCSs

468   defined with T_b, whereas it is at ~50% for MCSs defined with both T_b and precipitation. The

469   lower heavy rain ratio from the MCSs defined with T_b is caused by the more occurrences of

470   weak precipitation under the CCS cloud shields (Figures 6e-6g). These weak precipitation events

471   are more likely to be associated with stratiform-type precipitation rather than convective-type

472   strong precipitation in EAMv2, which is not the characteristics of MCS precipitation as in the

473   observations. The difference in simulated MCS precipitation also impacts the CCS lifetime

474   simulation. With the weaker simulated MCS strength, the CCS lifetime is also shorter for MCSs

475   defined with T_b than those defined with both T_b and precipitation.

476   We note that the simulated precipitation features (i.e., mean PF rain rate, total and heavy

477   rain volume) of tracked MCSs are more comparable between the model and the observation in

478   the Indo-Pacific region for MCSs defined with both T_b and precipitation than the T_b-only

479   definition, even though the annual mean MCS number and precipitation rate are substantially

480   underestimated. Although Figure 5 shows that the number of T_b-only defined MCSs is overall

481   comparable to the observed MCS number, the use of T_b-only method in MCS tracking could

482   include many weak convective events (i.e., suggested by the warm minimum T_b and low heavy

483   rain ratio). The inclusion of these weak convective systems can ultimately result in an

484   underestimation of the severity of MCS extreme precipitation by introducing a severe low bias in

485   the precipitation counted as MCSs.

486

487   **3.1.2. MCS over CONUS**

488   MCS precipitation was found to contribute more than 50% of total precipitation over the

489   CONUS region and can reach 70% in the central U.S. during the warm season (Feng et al., 2018,

490   2019). It is therefore imperative for GCMs to accurately simulate MCS precipitation in order to

491   understand and examine the impact of future climate change on MCS precipitation over the

492   CONUS. In this section, both the IMERG satellite precipitation data and the ground-based Stage

493   IV rain gauge measurements are analyzed to address the potential uncertainties in observational

494   datasets.

495   Figure 7 compares the mean total and MCS precipitation amount from March to August

496   over the CONUS region. Both IMERG and ground-based Stage IV observations indicate that

497   total precipitation peaks in the central CONUS (i.e., Kansas, Missouri, Oklahoma, and

498   Arkansas). Strong total precipitation is also found in southeast U.S. (i.e., Florida) in both

499   observations. Note that the strong total precipitation in the central U.S. is observed in both boreal

500   spring (MAM) and summer (JJA), while the southeast strong precipitation mainly occurs in the

501   summertime. Due to the higher horizontal resolution (native resolution of 4 km), the ground-

502   based data shows more fine-scale precipitation variability than the satellite data, but the general

503   precipitation patterns and magnitudes are similar in both datasets. For observed MCS

504   precipitation, both datasets present the peak MCS precipitation around the same regions where

505   strong total precipitation occurs in the central U.S. (i.e., the border of Kansas, Missouri,

506   Oklahoma, and Arkansas). Note that the difference between two MCS tracking methods is

507   negligible for observed MCS precipitation amount (Figures 7d-7e and Figures 7g-7h), same as

508   the tropical MCSs.

509   Compared to observations, the total precipitation peak simulated by the EAMv2 is mostly

510   located in the southeast U.S. and Florida. The simulated total precipitation is overestimated along

511   the southeast coasts, but the model significantly underestimates the strong precipitation in the

512   central U.S. This dry bias in the central U.S. is consistent with earlier studies (Cheruy et al.,

513   2014; Klein et al. 2006; Morcrette et al., 2018; Zheng et al., 2019). With the biased total

514   precipitation amount in EAMv2, simulated MCS precipitation defined with combined T_b and

515   precipitation is substantially underestimated in the CONUS region. Not only the MCS

516   precipitation magnitude is significantly weaker than the observed MCS precipitation, the spatial

517   coverage of MCS precipitation is also much smaller. Similar to the results from tropical MCS,

518   the MCS precipitation increases largely when using the T_b-only tracking method, in particular in

23

519   the southeast U.S. However, MCS remains significantly underestimated in the central CONUS

520   regardless which tracking method is used.

521   The biased MCS precipitation in EAMv2 is also reflected in the MCS precipitation

522   frequency over the CONUS (Figure 8). The simulated MCS precipitation frequency defined by

523   T_b and precipitation is substantially underestimated in the central U.S., while the frequency is

524   comparable to the observations in the southeast U.S. Although the impact of different MCS

525   tracking methods is small for observations, the MCS precipitation frequency is substantially

526   larger for MCSs from the T_b-only tracking in EAMv2. It is also shown in Figure 8f that the

527   frequency of occurrence of simulated MCSs defined with T_b becomes largely overestimated in

528   the eastern U.S.

529   Figure 9 compares the MCS number between EAMv2 and the observations in the

530   CONUS region. It is unsurprising to find the significant underestimation of MCS number in

531   EAMv2 over the entire CONUS when MCSs are defined using the combined method. On the

532   other hand, the impact of MCS definition on simulated and observed MCS number is again

533   consistent with the global MCS number in Figure 5. For example, the MCS number over the

534   CONUS region in both the IMERG and Stage-IV observations remains similar between two

535   definitions (Figures 9a-9b and 9d-9e), but the simulated MCS number from T_b-only method

536   becomes more comparable to the observation in EAMv2, although the location of MCS number

537   peaks is misrepresented. However, we note that the good agreement is a result of less accurate

538   tracking of MCSs.

539   The PDFs of MCS properties over the central CONUS region are shown in Figure 10. In

540   general, the statistics of MCS properties are comparable between the two observations. This is

541   the case especially for cloud shield related properties such as CCS lifetime, maximum CCS area,

542   and minimum cloud-top T_b throughout the lifetime, which implies the small uncertainty in these

543   observed CCS properties in different datasets. On the other hand, larger differences are found in

544   the PDFs of precipitation related properties (i.e., maximum PF area, mean rain rate, rain volume,

545   and heavy rain ratio). For instance, the IMERG data shows larger PF area and higher rain

546   volume, but lower mean rain rate and heavy rain ratio compared to the ground-based

547   measurements, consistent with previous studies (Cui et al., 2020; Zhang et al., 2021; Ayat et al.,

548   2021). Compared to the observations, it is similar to the tropical MCSs that the simulated CCS

549   lifetime is longer than observed (Figure 10a) and the simulated cloud-top minimum T_b is warmer

550   (Figure 10c) over the CONUS region. EAMv2 simulated MCSs contain substantially weaker rain

551   rate (Figure 10e) and lower heavy rain ratio (Figure 10h) than observations. However, different

552   from the tropical region, the simulated maximum CCS area and PF area are larger than both

553   observations (Figures 10b and 10d), which leads to larger total and heavy rain volume within the

554   MCS cloud shields (Figures 10f and 10g) over the CONUS. We note that the biases in rain rate

555   and convective strength (i.e., implied by the minimum T_b) are the primary reasons for the

556   underestimated MCS precipitation in the CONUS region.

557   Figure 10 shows that the differences in observed MCS properties between two tracking

558   methods are again insignificant, similar to the Indo-Pacific region (Figure 6). This indicates the

559   robustness of the MCS tracking methods in identifying warm season MCSs in observations. On

560   the other hand, the statistics of model simulated MCS properties are more sensitive to the MCS

561   definition with precipitation. In contrast to the Indo-Pacific region, all the simulated MCS

562   properties show large sensitivities to the MCS definition. The difference from the Indo-Pacific

563   region exists in the maximum CCS area and PF area, which suggests the impact of MCS

564   definition on CCS identification in the central U.S. But again, the simulated PF characteristics

565   such as the PF rain rate and heavy rain ratio are significantly weaker for MCSs defined with T_b

566   than the combined method. Note that our analysis suggests that EAMv2 does not show an

567   improvement in simulating MCSs compared to EAMv1, in which the MCS precipitation amount,

568   frequency of occurrence, and number are all underestimated compared to observations from

569   March to May (Wang et al., 2021).

570   Similar MCS evaluation was made in Dong et al. (2023) to evaluate the GCM (uniform

571   50 km horizontal resolution) simulated MCS properties in the CONUS region. Based on the

572   MCS samples tracked using only T_b, they found that the model well reproduces the spatial

573   distribution of occurrence frequency of MCS and the MCS duration, MCS strength, size, and

574   movement speed. However, given the differences between two MCS tracking methods analyzed

575   in the current study, without considering surface precipitation features in the MCS tracking

576   might lead to different conclusions in the evaluation of model skills in simulating MCSs and

577   associated precipitation characteristics. For example, large-scale predominantly stratiform

578   precipitation associated with synoptical-scale cloud bands (e.g., low pressure or frontal systems)

579   may be included in the sampled MCSs when surface precipitation is not accounted for. Together

580   with the similar findings in the global analysis, our study suggests the importance of including

581   precipitation characteristics in the MCS definition and tracking when evaluating MCS properties

582   in GCMs.

583

584   **3.2. Impact of cloud and convection parameterizations**

585   The previous sections have shown that EAMv2 is not capable of reproducing the

586   observed MCS properties in the tropics and the CONUS region. In this section, we examine four

587   new cloud and convection parameterizations (described in Section 2.2) that are developed for

588   EAMv3 to see if these new developments will lead to an improvement in the E3SM simulated

589   MCSs. The sensitivity tests on each of the four new features are examined to understand their

590   individual impacts on the MCS simulation. Note that the sensitivity test with all new features

591   combined was also examined. However, because the combined impact of all new features on

592   MCS simulation is dominated by P3 and MAdj, we do not include this sensitivity experiment in

593   this discussion. Based on the MCS evaluation in the earlier sections, we find that the MCS

594   tracking method using only T_b overestimates the model's capability in capturing MCSs for

595   E3SMv2. Therefore, we focus our discussion on results using the more stringent MCS tracking

596   method with both T_b and surface precipitation in this section.

597   The spatial distribution of annual mean total precipitation and MCS precipitation

598   differences between EAMv2 sensitivity experiments and the default EAMv2 physics (CTL

599   hereafter) is shown in Figure 11. In general, the impact of these new cloud and convection

600   schemes on the simulated total precipitation is minor over most regions for the MCSP and

601   ZMmicro experiments, but noticeable impacts are found in the sensitivity experiments of P3 and

602   MAdj. For example, using P3 cloud microphysics largely increases the total precipitation

603   simulated over the subtropical western Pacific Ocean and SPCZ compared to CTL, but the total

604   precipitation is decreased in the central and eastern Pacific Ocean and tropical Indian Ocean.

605   Similar effects on total precipitation are also found with the cloud base mass flux adjustment test

606   in the tropical ocean, but the changed precipitation amount is much smaller than P3. Meanwhile,

607   the deep convective cloud microphysics in the ZM scheme only slightly increases tropical total

608   precipitation, and the impact of MCSP is minimal.

609   Similar impact is seen in the simulated MCS precipitation. For example, P3 largely

610   increases the MCS precipitation in the subtropical western Pacific Ocean while it leads to a

611   reduction in the Indian Ocean and equatorial central and eastern Pacific Ocean. It is interesting

612   that MAdj leads to a reduction of MCSs over oceans globally, particularly over the ITCZ and

613   SPCZ regions. The increased and decreased MCS precipitation due to P3 and MAdj both enlarge

614   the existing MCS precipitation biases identified in CTL shown in Figure 2. We note that the

615   reduced MCS precipitation in the ITCZ region is more significant for the MCSs defined using

616   combined T_b and surface precipitation than the MCSs defined with T_b (not shown). By

617   examining the PDF of hourly precipitation rate in the tropics where MCS precipitation

618   substantially increased for P3 (Figures 12e), we indeed find that compared with CTL where

619   MG2 is used, P3 tends to largely increase the occurrences of heavy precipitation rate (rain rate >

620   5 mm hr^{-1}) because of the accounted riming (Wang et al., 2021). The increased heavy

621   precipitation rate becomes most comparable to observations among all sensitivity experiments.

622   However, P3 presents less degree of improvement in simulated heavy rain rate compared to CTL

623   over other regions (Figures 12d). This suggests that the change in simulated MCS precipitation is

624   primarily driven by the variation in simulated heavy precipitation rate. On the other hand, the

625   simulated frequency of heavy rain rate is significantly lower in MAdj than CTL. This explains

626   why MCS precipitation becomes substantially weaker in the tropics in MAdj. The reduced heavy

627   rain frequency in MAdj is possibly the result of more convection formation in the low CAPE

628   environment using the new cloud base mass flux adjustment treatment. Both MCSP and

629   ZMmicro show little impacts on MCS precipitation compared to CTL.

630   To further diagnose the reasons of model behavior change in simulating tropical

631   precipitation, Figure 13 shows the global annual mean relative contribution of convective

632   precipitation to total precipitation in CTL and sensitivity experiments. It is shown in Figure 13a

633   that the total precipitation is primarily generated by large-scale precipitation in the western

634   Pacific Ocean and tropical Indian Ocean, while the convective precipitation mainly contributes

635   to the precipitation in the tropical eastern Pacific Ocean. The substantial contribution of large-

636   scale precipitation to total precipitation in CTL is somehow counterintuitive, particularly for the

637   tropical convective systems. It also probably explains the underestimated heavy precipitation in

638   simulated MCSs. In sensitivity experiments, it is interesting to note that both P3 and MAdj

639   largely increase the convective precipitation fractions in the tropics compared to CTL. Although

640   ZMmicro slightly decreases the convective precipitation fraction over the subtropical ocean in

641   the southern hemisphere, the impacts of MCSP and ZMmicro on convective precipitation

642   fraction is overall insignificant in the tropics. In addition, with larger convective precipitation

643   fraction in P3 and MAdj, the occurrences of large convective precipitation rate are also increased

644   compared to CTL (Figures 12c and 12f). However, the magnitude of convective precipitation

645   rate remains lower than large-scale precipitation rate by more than a factor of 5. The increased

646   convective precipitation fraction but the weak convective precipitation from P3 and MAdj

647   suggest that the precipitation formation in convective scheme is likely not strong enough to

648   produce sufficient heavy precipitation to be counted as MCSs, which therefore causes the

649   underestimated MCS precipitation in the model.

650   Figure 14 shows the individual impacts of new physics features on the total and MCS

651   precipitation simulation over the CONUS region. In general, P3 microphysics tends to further

652   worsen the underestimated total precipitation in the central U.S., except for Arkansas, Louisiana,

653   and Mississippi, while all other three schemes generally show positive effects to increase

654   simulated total precipitation compared to CTL. In terms of the simulated MCS precipitation,

655   although P3, MCSP, and ZMmicro all tend to increase the MCS precipitation rate, the magnitude

656   is too small to have a meaningful impact on the largely underestimated MCS in EAMv2.

657   In summary, the sensitivity experiments suggest that these newly implemented cloud and

658   convection features are likely not to help improve the simulation of MCS in the next version of

659   E3SM. A higher model resolution (i.e., km-scale) for the model to better resolve heavy

660   precipitation processes for MCSs or the better representation of mesoscale dynamics and physics

661   in cloud and convection parameterizations are needed.

662

4. Summary and discussion

664   This study evaluates the MCS simulation in EAMv2 model using uniform high resolution

665   (~0.25°) model configuration. We use the recently developed PyFLEXTRKR MCS tracking

666   algorithm, which considers both cloud-top T_b and surface precipitation to track global MCS

667   evolution and evaluate the statistics of MCS properties simulated in EAMv2 against

668   observational datasets. The MCSs defined purely based on cloud-top T_b, which is commonly

669   used in previous studies, are also examined to understand the impact of different MCS

670   definitions on the MCS evaluation.

671   In the tropical region, EAMv2 reasonably simulates the total precipitation in the

672   equatorial central and eastern Pacific Ocean, but it underestimates the total precipitation over the

673   tropical Indian Ocean and Maritime Continent region. For the simulated MCS precipitation,

674   EAMv2 largely underestimates the tropical MCS precipitation compared to the observations. The

675   underestimation is more substantial in the tropical Indian Ocean and Maritime Continent,

676   indicating that the dry bias in the total precipitation over the region is primarily due to the lack of

677   MCS precipitation. Simulated MCS precipitation fraction is thus also substantially

678   underestimated. EAMv2 shows that the simulated frequency of occurrence is comparable to the

679   observations in the central Pacific Ocean along the equator, while it substantially underestimates

680   MCS occurrences in the tropical Indian Ocean and Maritime Continent. The simulated MCS

681   frequency of occurrence in the eastern equatorial Pacific Ocean, on the other hand, is found

682   slightly higher than observations even though the MCS precipitation rate over the region is

683   slightly underestimated. This is because the model CCS lifetime is longer than the observed

684   MCSs.

685   Over the CONUS region, EAMv2 also substantially underestimates the MCS

686   precipitation rate and MCS precipitation occurrences in the central U.S. in both spring and

687   summer seasons. Note that EAMv2 shows problems in simulating MCSs in both magnitude and

688   location. We find that EAMv2 simulated MCS is dominant in the southeast U.S., but the model

689   significantly misses the MCS occurrence in the central U.S.

690   Our analysis also shows that the MCS number is substantially higher by using the T_b-only

691   tracking, which includes cloud systems with weak surface precipitation that may not be

692   associated with MCSs. As a result, the MCS precipitation amount and frequency are also largely

693   increased by using the T_b tracking. The largest impact is found in the tropical Africa and

694   Amazon lands and the southeast U.S., where simulated MCS number detected by T_b becomes

695   comparable to the observations. This indicates using the T_b tracking method could overestimate

696   the model's capability in simulating MCSs. It is thus important to include precipitation

697   characteristics in MCS definition when evaluating MCS properties in GCMs. It also points out

698   that the biases in simulating MCSs in EAMv2 is mainly due to the underestimation of MCS

699   precipitation intensity. Additionally, we also find that the simulated MCS number is slightly

700   increased in the tropics when we reduce the lifetime-dependent tunable PF parameters (i.e.,

701   smaller slopes of coefs_pf_area, coefs_pf_rr, and coefs_pf_skew in Table A1) used in the

702   tracking (not shown). This further suggests the sensitivity of simulated MCS number to the

703   precipitation associated tracking parameters. Compared to the MCS precipitation, the model can

704   reasonably simulate the mesoscale cloud shield structures (CCS area) at 0.25° horizontal

705   resolution.

706   To examine the impact of model physics on the simulation of MCS, four sensitivity

707   experiments are performed with the new cloud and convection parameterizations that are

708   developed for EAMv3. These include the P3 microphysics, MCSP, convective cloud

709   microphysics, and cloud base mass flux adjustment. Our analysis shows little impact on the

710   simulation of MCSs using these new features at 0.25° horizontal resolution. Only the P3 cloud

711   microphysics scheme presents a notable improvement in the simulated MCS precipitation in the

712   subtropical western Pacific Ocean. This indicates that the MCS simulation will likely remain a

713   challenge in the next version of EAM at the mesoscale resolution. However, it is interesting to

714   note that both P3 and cloud base mass flux adjustment treatment largely increase the convective

715   precipitation contribution to total precipitation in the tropics. This increased convective

716   precipitation fraction is physically more reasonable, but the remaining issue in simulating heavy

717   precipitation in MCSs is likely caused by the insufficient strong precipitation formation in the

718   convective scheme.

719   Over the CONUS region, P3, MCSP, and deep convective cloud microphysics all tend to

720   enhance the simulated MCS precipitation in the central U.S., but the change is overall minimal.

721   However, we note that Wang et al. (2021) suggested that the use of P3 scheme substantially

722   improves the MCS number and precipitation over the CONUS region in the RRM version of

723   E3SMv1. The minimal impact of P3 based on EAMv2 model configuration tested in this study

724   suggests that the performance of parameterizations could also depend on model configurations

725   and other physics parameterizations used in the model. Furthermore, our results are consistent

726   with Feng et al. (2021b) who also tracked MCS using both T_b and precipitation feature and found

727   weak MCS precipitation intensity and underestimated MCS number over CONUS in simulations

728   at 25 km and 50 km resolution. Tracking MCS using both T_b and precipitation in the NICAM

729   (Nonhydrostatic ICosahedral Atmospheric Model) simulations at 14 km resolution, Na et al.

730   (2022) also found underestimated MCS number over the CONUS during summer. Without the

731   use of any cumulus parameterizations, the NICAM simulation produced stronger MCS

732   precipitation, smaller precipitation area, and larger cold cloud system than those observed. Both

733   Feng et al. (2021b) and Na et al. (2022) attributed the MCS biases over CONUS to the dry bias

734   in the lower atmosphere. Recent studies suggested that the dry bias in the atmospheric boundary

735   layer could result from biases in land surface models and land-atmosphere interactions (Barlage

736   et al., 2021; Qin et al., 2023). Future direction of improving MCS simulation in E3SM involves

737   both increasing model resolution to better resolve key dynamical processes and improving model

738   physics to better represent MCSs.

1141

1142   Table 1. Model simulations used in evaluation.

1143

Model experiments	Description
CTL	Default EAMv2 model simulation at 0.25° horizontal resolution.
P3	Based on CTL, including P3 cloud microphysics scheme.
ZMmicro	Based on CTL, with two-moment cloud microphysics in ZM convection scheme.
MCSP	Based on CTL, with Multi-scale Coherent Structure Parameterization.
MAdj	Based on CTL, with cloud base mass flux adjustment treatment in ZM convection scheme.

1144

1145

1146

1147

1148

1149   Table 2. Observations used in evaluation.

1150

Data name	Horizontal resolution	Coverage area	Data period	Note for MCS tracking
NASA Global Merged IR V1 infrared T_b product	4 km	60°S-60°N	2005-2009	Used as the T_b data source for both global and CONUS MCS tracking
GPM Integrated Multi-satelliteE Retrievals (IMERG) V06B precipitation data	10 km	60°S-60°N	2005-2009	Used as surface precipitation data source for global MCS tracking
NEXRAD radar and Stage IV multisensor precipitation data	4 km	CONUS	2005-2009	Used as surface precipitation data source for CONUS MCS tracking

1151   Note: T_b and precipitation data are regridded to 0.25° (~25 km) horizontal resolution to match
1152   the model grid spacing.
1153
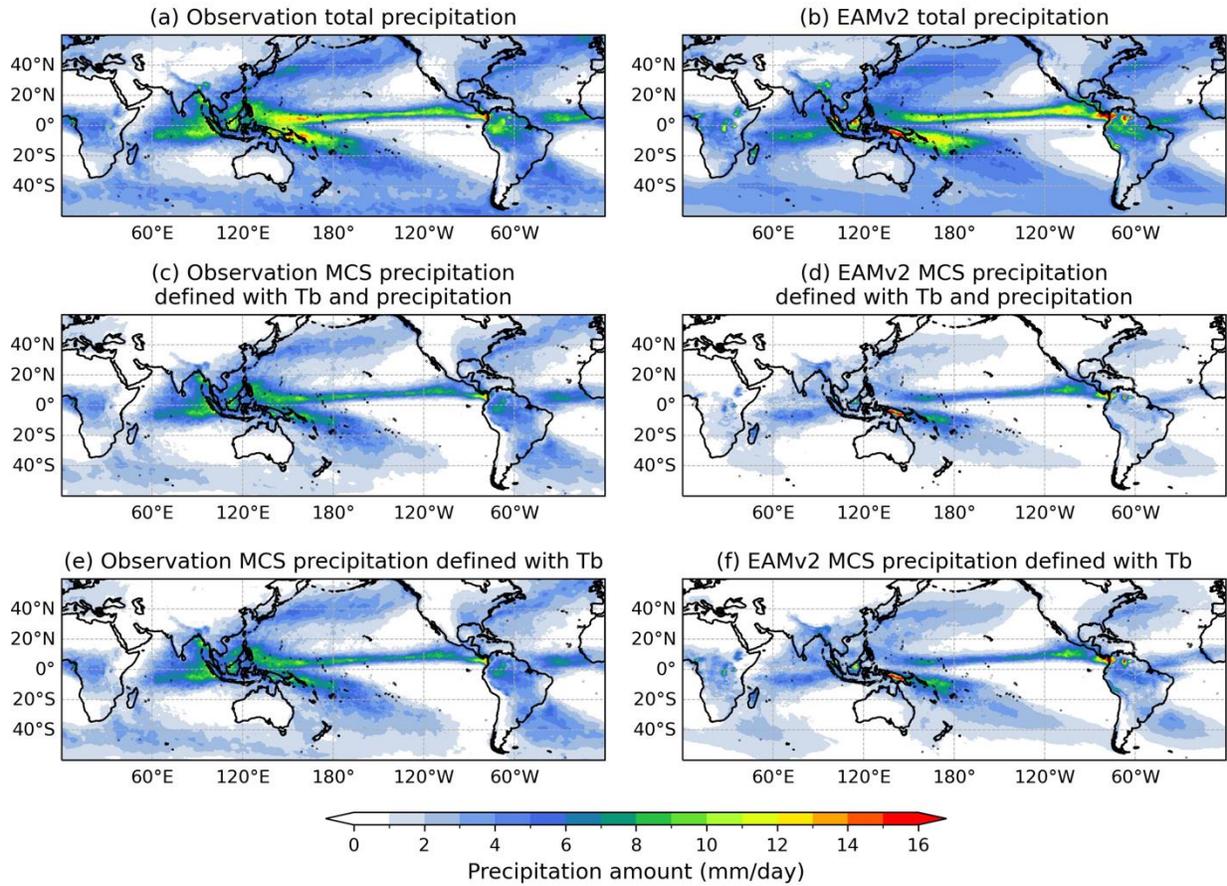

Figure 1. Maps of annual mean total precipitation amount (a, b), MCS precipitation amount defined with T_b and precipitation tracking method (c, d), MCS precipitation amount defined with T_b only tracking method (e, f), The IMERG observation is shown on the left while EAMv2 simulation is on the right. Model and observations cover between 2005 and 2009.
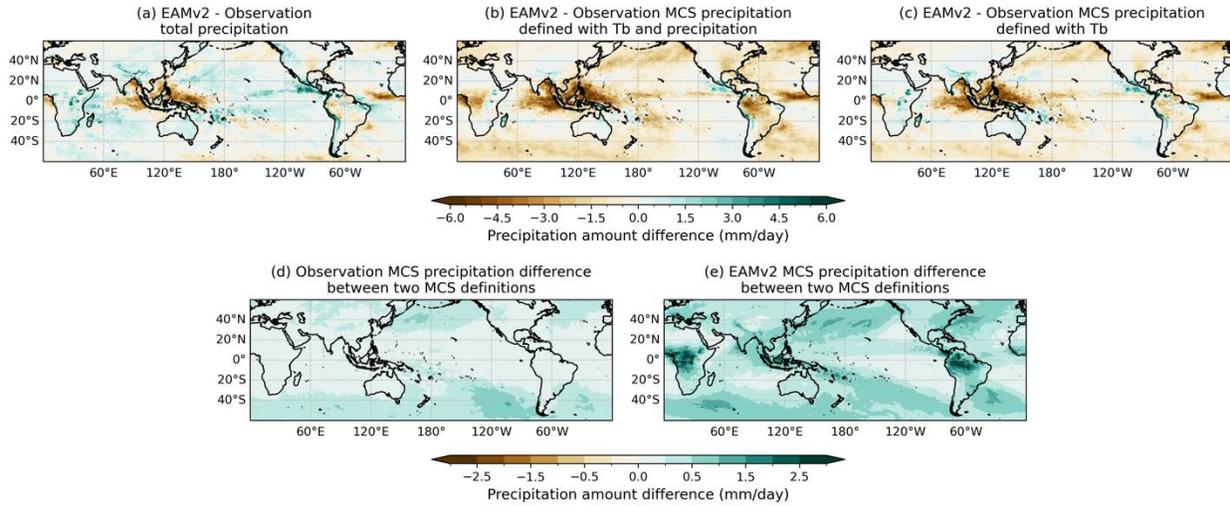

Figure 2. Maps of annual mean total precipitation bias (a), MCS precipitation bias defined using T_b and surface precipitation (b), MCS precipitation bias defined using T_b only in EAMv2 compared to the IMERG observation. The MCS precipitation difference between two tracking methods is shown in (d) for the IMERG observation and (e) for EAMv2. The MCS precipitation differences in (d) and (e) are calculated by subtracting T_b and precipitation combined method from T_b only method for tracked MCSs.
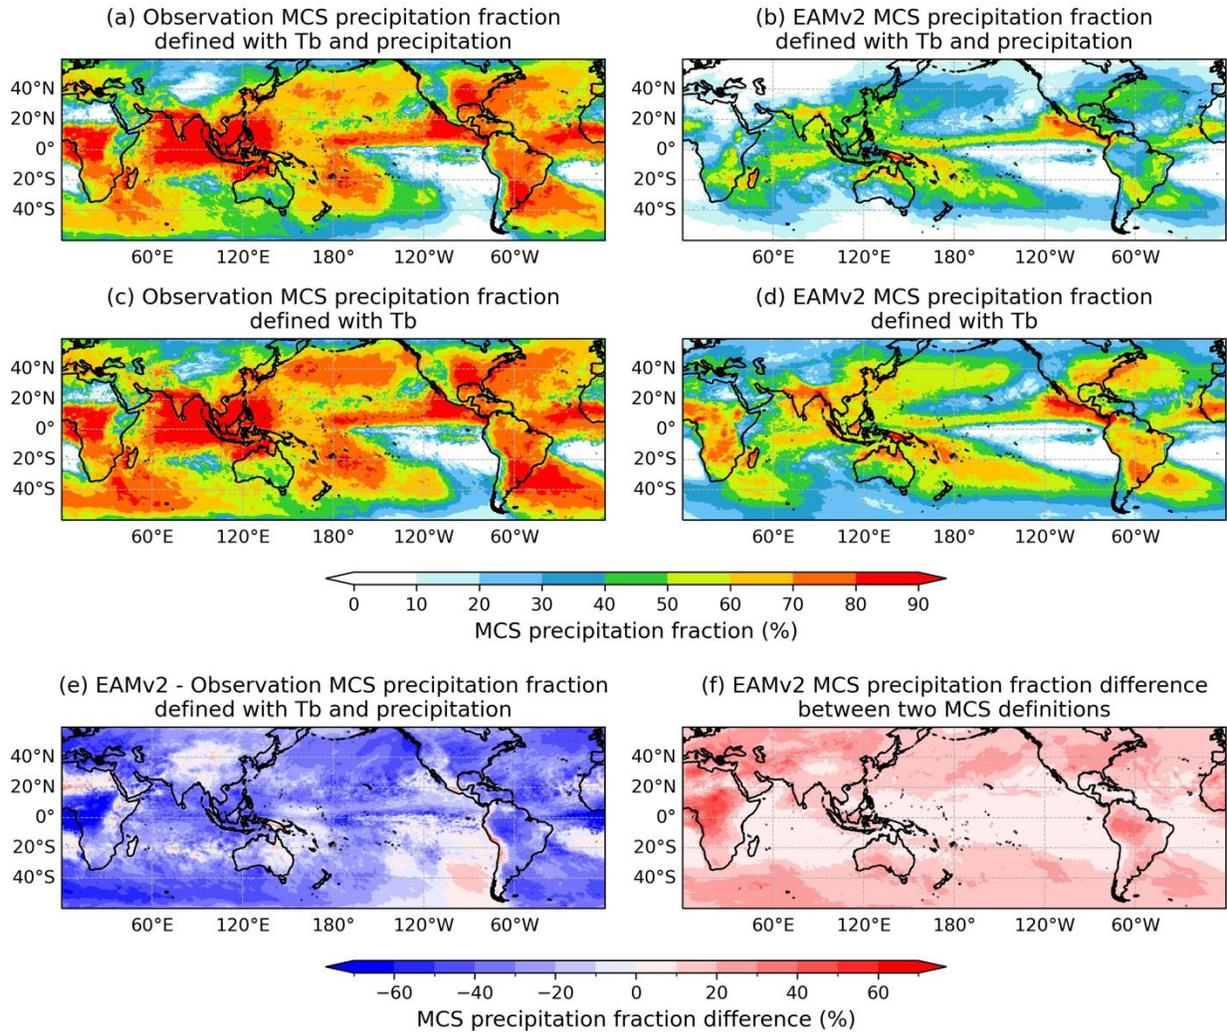

1170
1171 Figure 3. Maps of annual mean MCS precipitation fraction defined using T_b and surface
1172 precipitation (a, b) and MCS precipitation fraction defined using T_b only (c, d). The IMERG
1173 observation is shown on the left and EAMv2 simulation is shown on the right. (e) shows the
1174 MCS precipitation fraction bias defined using T_b and precipitation, which is (b) minus (a). (f)
1175 shows the MCS precipitation fraction difference between two tracking methods in EAMv2,
1176 which is (d) minus (b). The MCS precipitation fraction is calculated by dividing MCS
1177 precipitation by total precipitation.
1178

1179

1180

1181
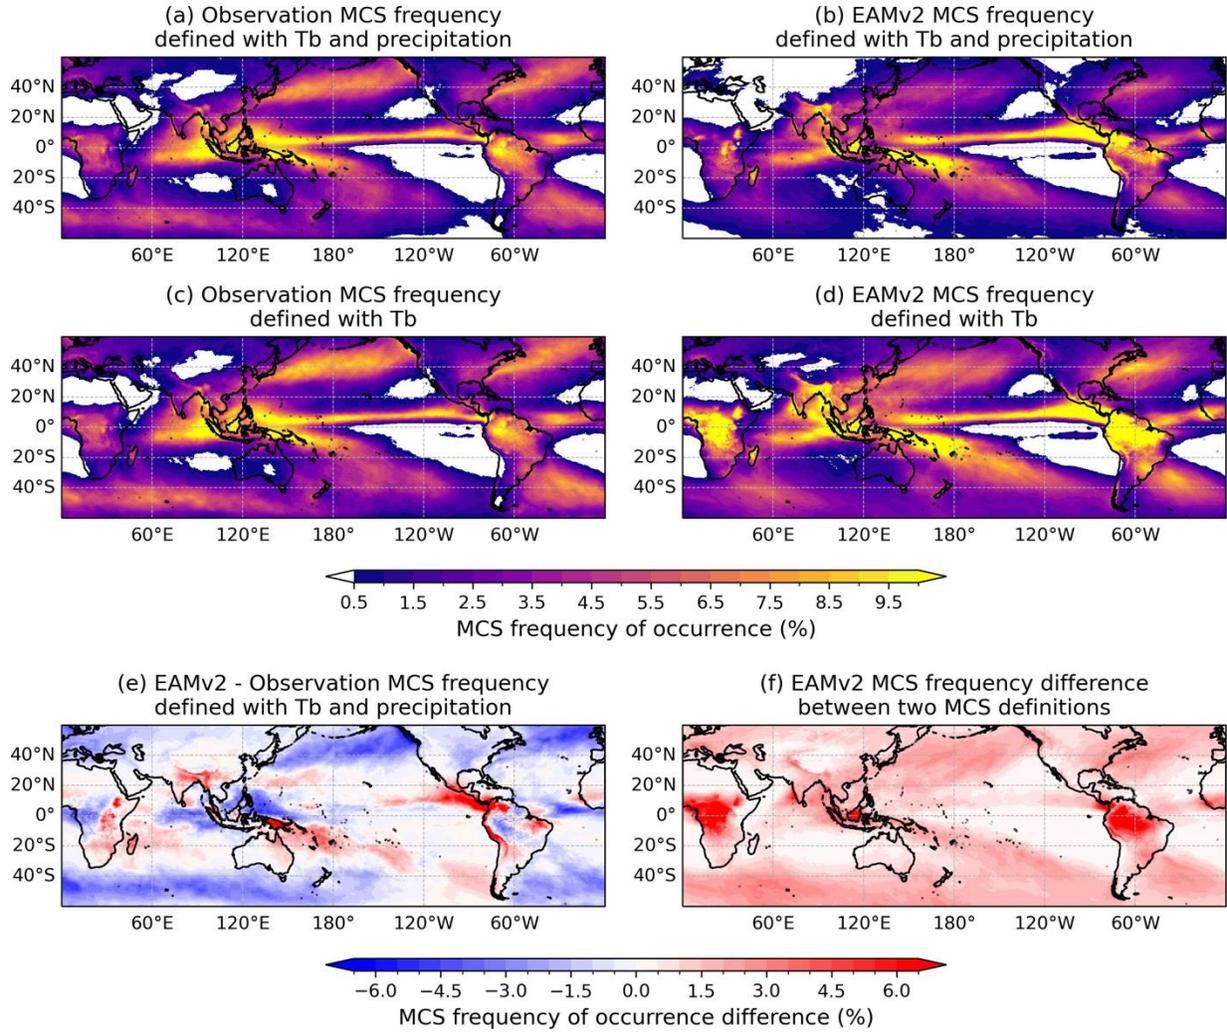

Figure 4. Maps of annual mean MCS precipitation frequency defined using T_b and surface precipitation (a, b) and MCS precipitation frequency defined using T_b only (c, d). The IMERG observation is shown on the left and EAMv2 simulation is shown on the right. (e) shows the MCS precipitation frequency bias defined using T_b and precipitation, which is (b) minus (a). (f) shows the MCS precipitation frequency difference between two tracking methods in EAMv2, which is (d) minus (b). MCS precipitation frequency is defined as the ratio of total hours of MCS precipitation to total hours between 2005-2009.
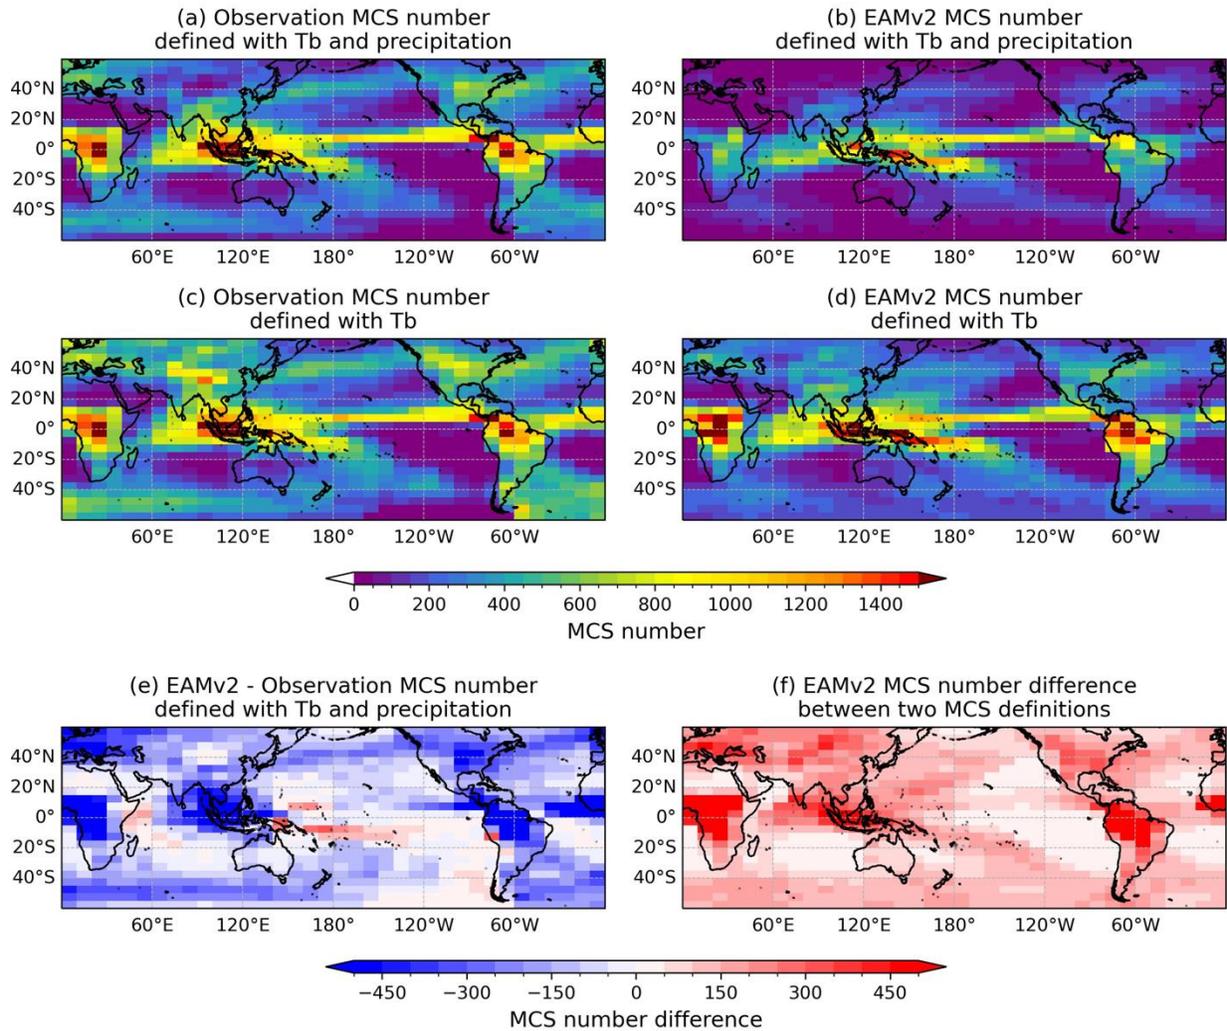

1191
1192   Figure 5. Maps of annual mean MCS number defined using T_b and surface precipitation (a, b)
1193   and MCS number defined using T_b only (c, d). The IMERG observation is shown on the left and
1194   EAMv2 simulation is shown on the right. (e) shows the MCS number bias defined using T_b and
1195   precipitation, which is (b) minus (a). (f) shows the MCS number difference between two tracking
1196   methods in EAMv2, which is (d) minus (b). MCS number is counted as the number of unique
1197   latitude/longitude pairs of each MCS track within the 5° × 10° latitude/longitude grids.
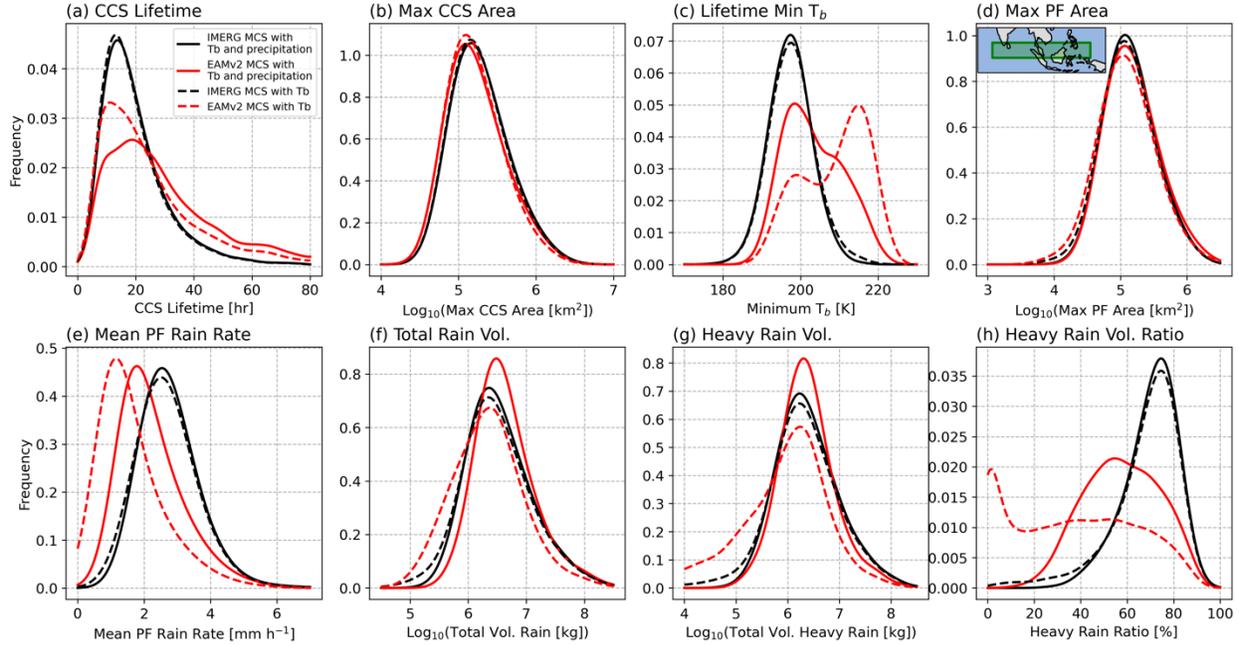

Figure 6. The PDFs of (a) cold cloud system lifetime, (b) maximum cold cloud system area throughout the MCS lifetime, (c) minimum cloud top brightness temperature throughout the MCS lifetime, (d) maximum precipitation feature area, (e) mean rain rate within the precipitation feature domain, (f) total rain volume, (g) heavy rain (rain rate > 2 mm h^{-1}) volume, and (h) heavy rain volume ratio over the Indo-Pacific region. Black lines represent the IMERG observation, and red lines represent the EAMv2 model simulation. Solid lines are for MCSs defined using combined T_b and surface precipitation, and dashed lines are for MCSs defined using only T_b. The PDFs are calculated in the Indo-Pacific domain indicated by the green box in panel (d).
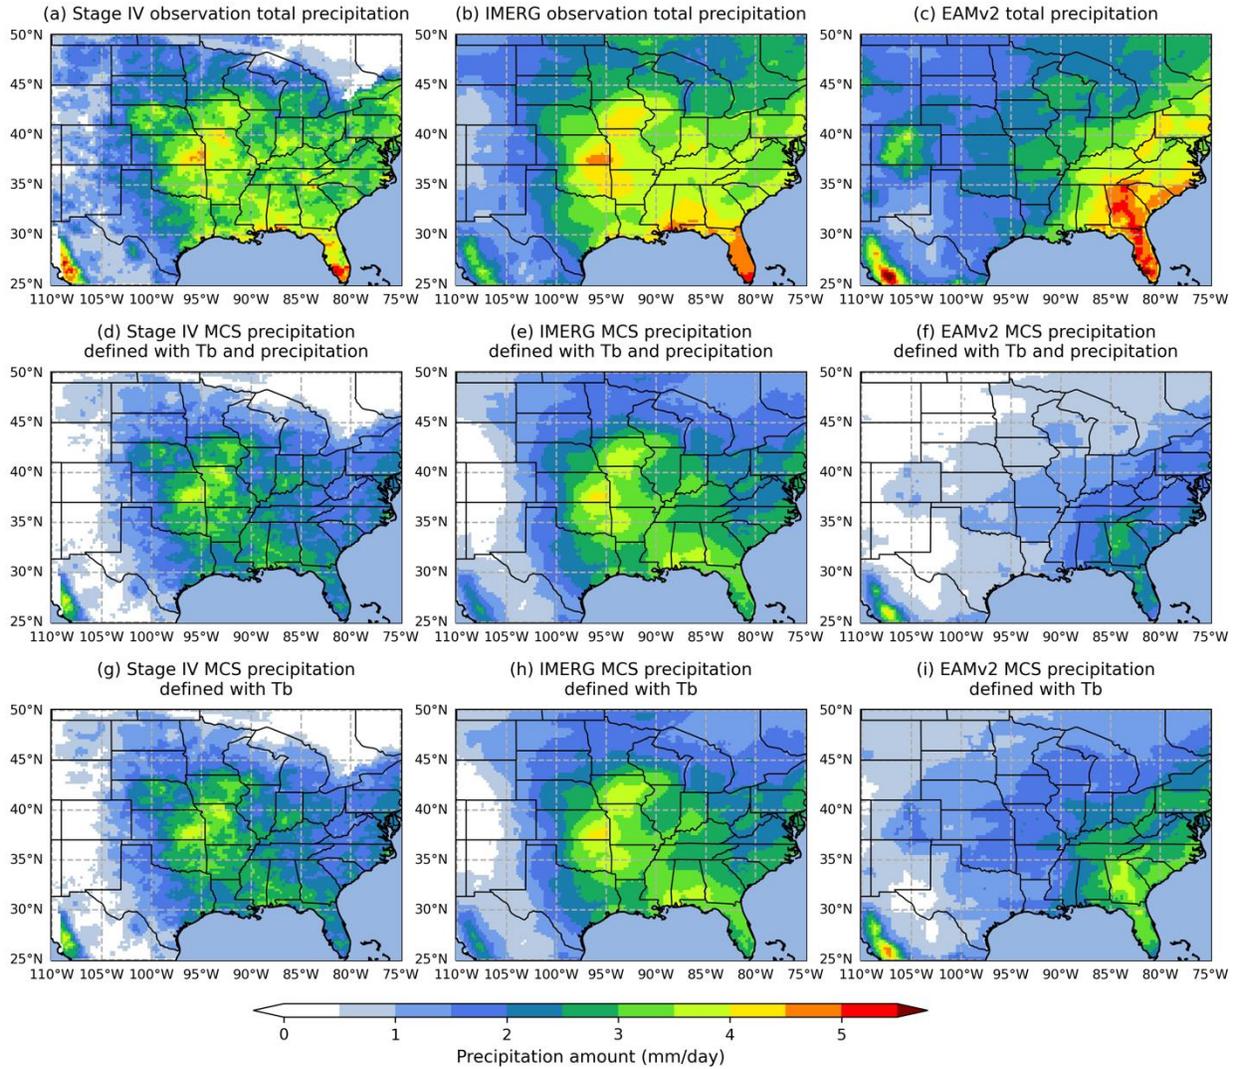

Figure 7. Maps of mean total precipitation amount (a-c), MCS precipitation amount defined using combined T_b and surface precipitation (d-f), and MCS precipitation amount defined using only T_b (g-i) from March to August between 2005 and 2009 over the CONUS region. Precipitation observations from the Stage IV precipitation gauge (left) and from the IMERG satellite retrieval (middle) are compared with the EAMv2 simulations (right).
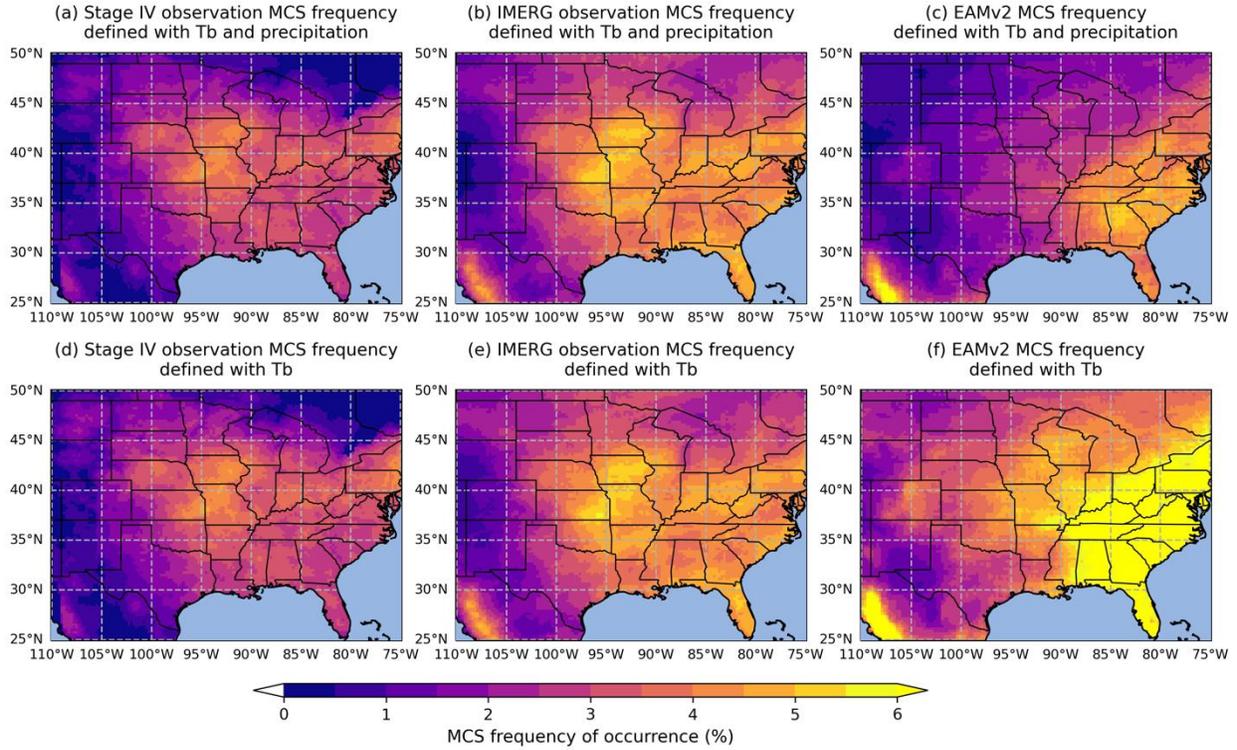

Figure 8. Maps of mean MCS precipitation frequency defined using combined T_b and surface precipitation (a-c) and MCS defined using only T_b (d-f) from March to August between 2005 and 2009 over the CONUS region. Observations from the Stage IV precipitation gauge (left) and from the IMERG satellite retrieval (middle) are compared with the EAMv2 simulations (right).
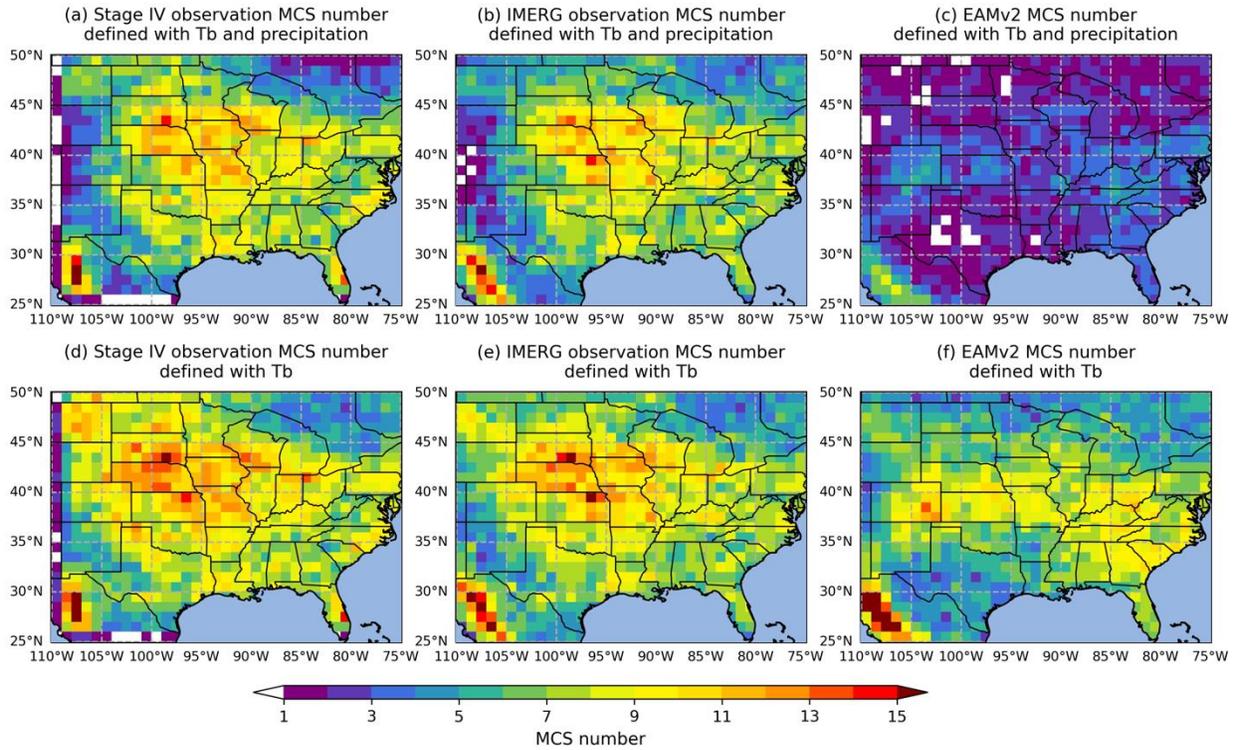

Figure 9. Maps of mean MCS number of MCS defined using combined T_b and surface precipitation (a-c) and MCS defined using only T_b (d-f) over the CONUS region. Observations from the Stage IV precipitation gauge (left) and from the IMERG satellite retrieval (middle) are compared with the EAMv2 simulations (right). The MCS number is calculated as the number of unique latitude/longitude pairs of each MCS track within the $1° \times 1°$ latitude/longitude grids from March to August between 2005 and 2009.
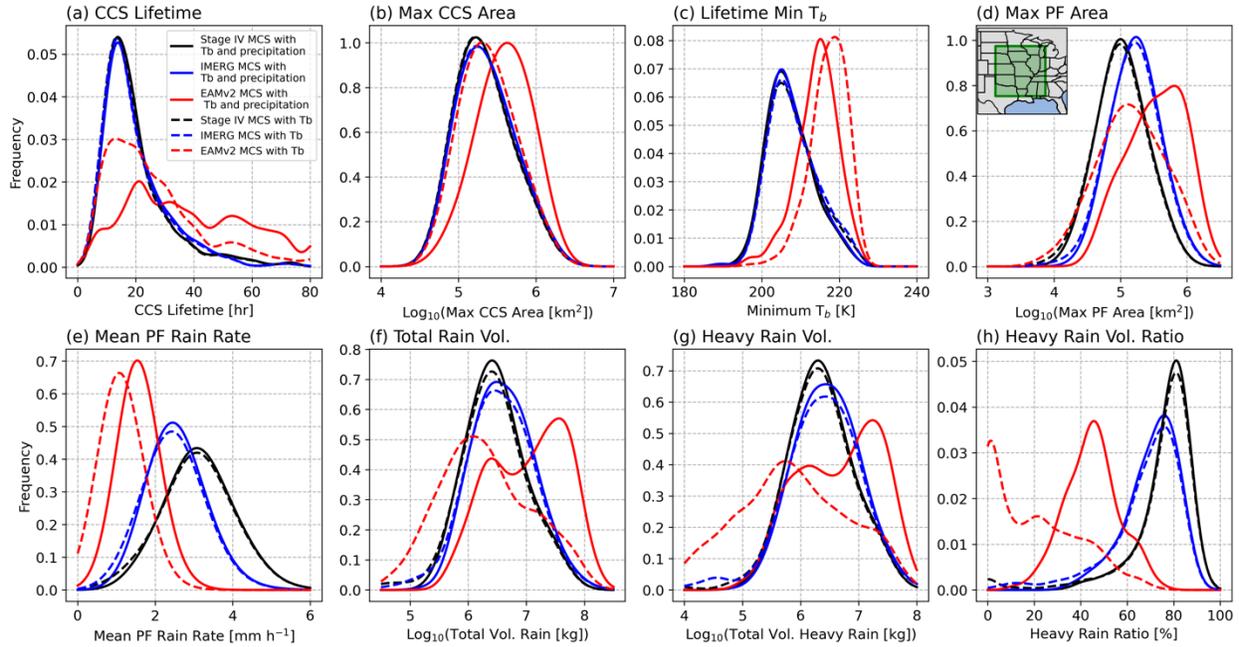

1228
1229 Figure 10. Same as Figure 6, but the PDFs are calculated in the central U.S. domain shown in
1230 panel (d). Black lines represent observations using ground-based measurements. Blue lines
1231 represent the IMERG precipitation data. Black lines represent EAMv2 model simulations.
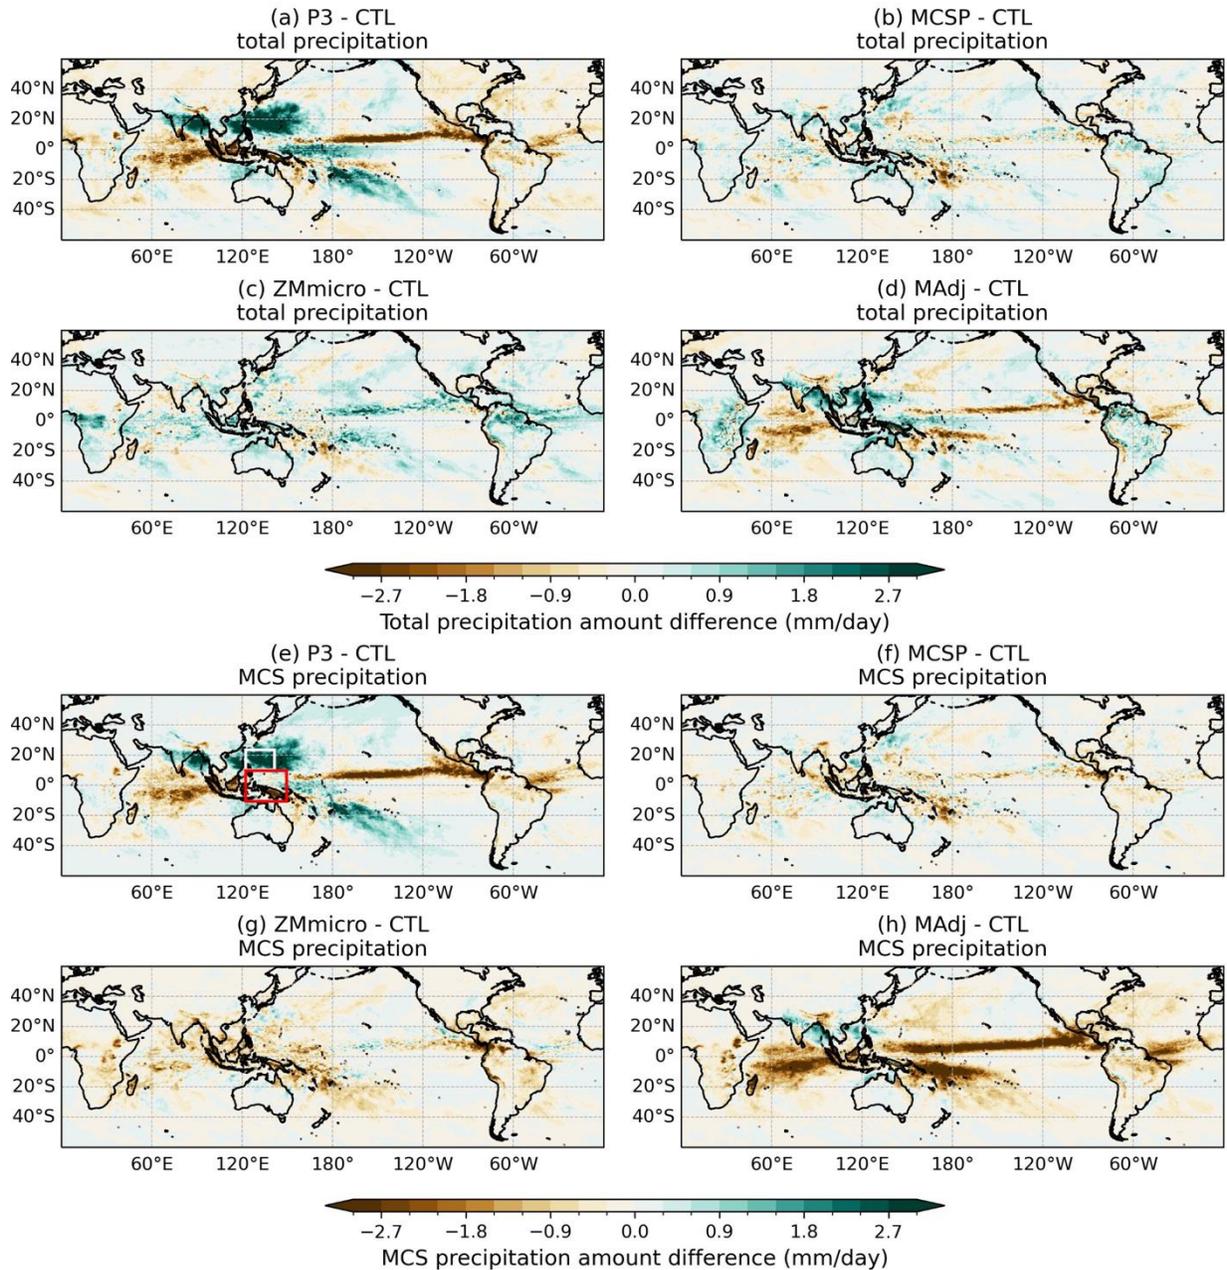

Figure 11. Maps of annual mean total precipitation rate difference (a-d) and MCS precipitation rate difference defined using combined T_b and surface precipitation (e-h) between 2005 and 2009. (a)-(d) and (e)-(h) are the differences between individual new physics feature (i.e., P3 cloud microphysics, MCSP, convective microphysics scheme in ZM, and cloud base mass flux adjustment) and CTL simulations, respectively. White and red boxes are the areas used to calculate rain rate PDFs in Figure 13.
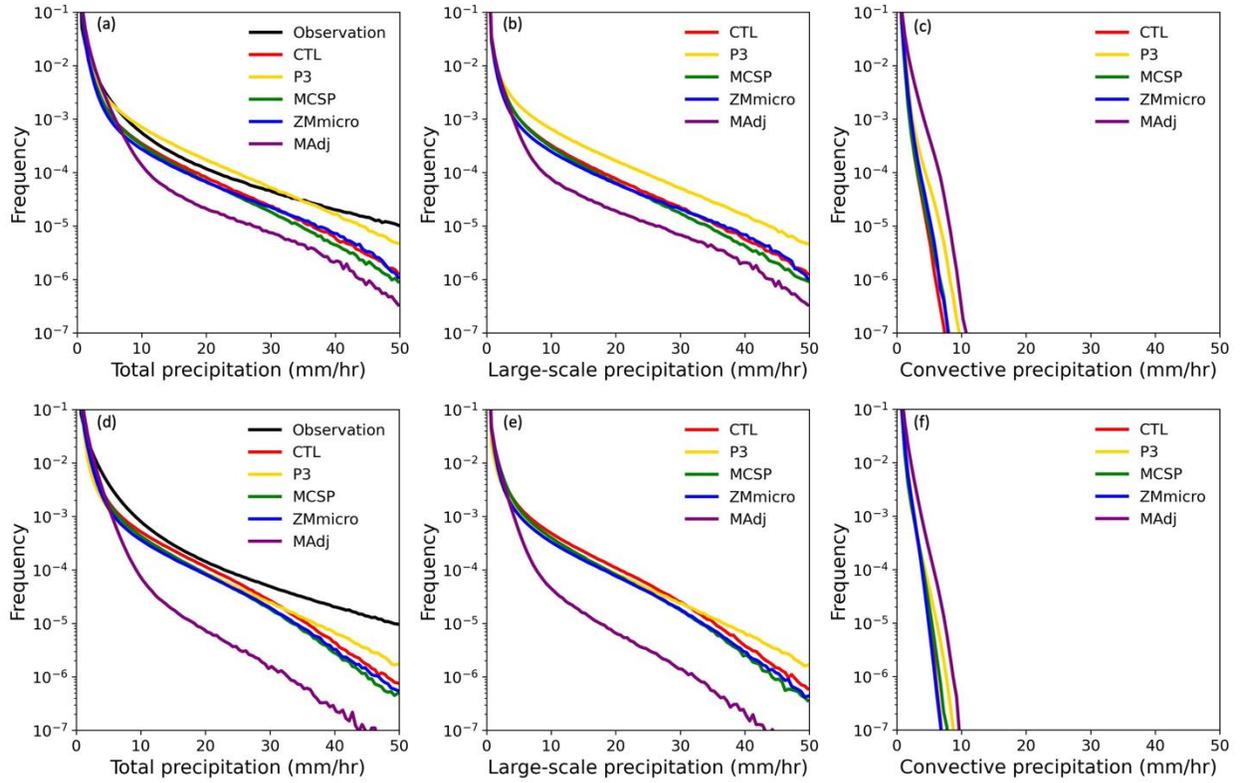

Figure 12. Probability density functions of hourly total, large-scale, and convective precipitation rates between 2005 and 2009 sampled over the white box domain (a-c) and red box domain (d-f) in Figure 11. The IMERG observation and EAMv2 model simulations with CTL and new physics features are shown.
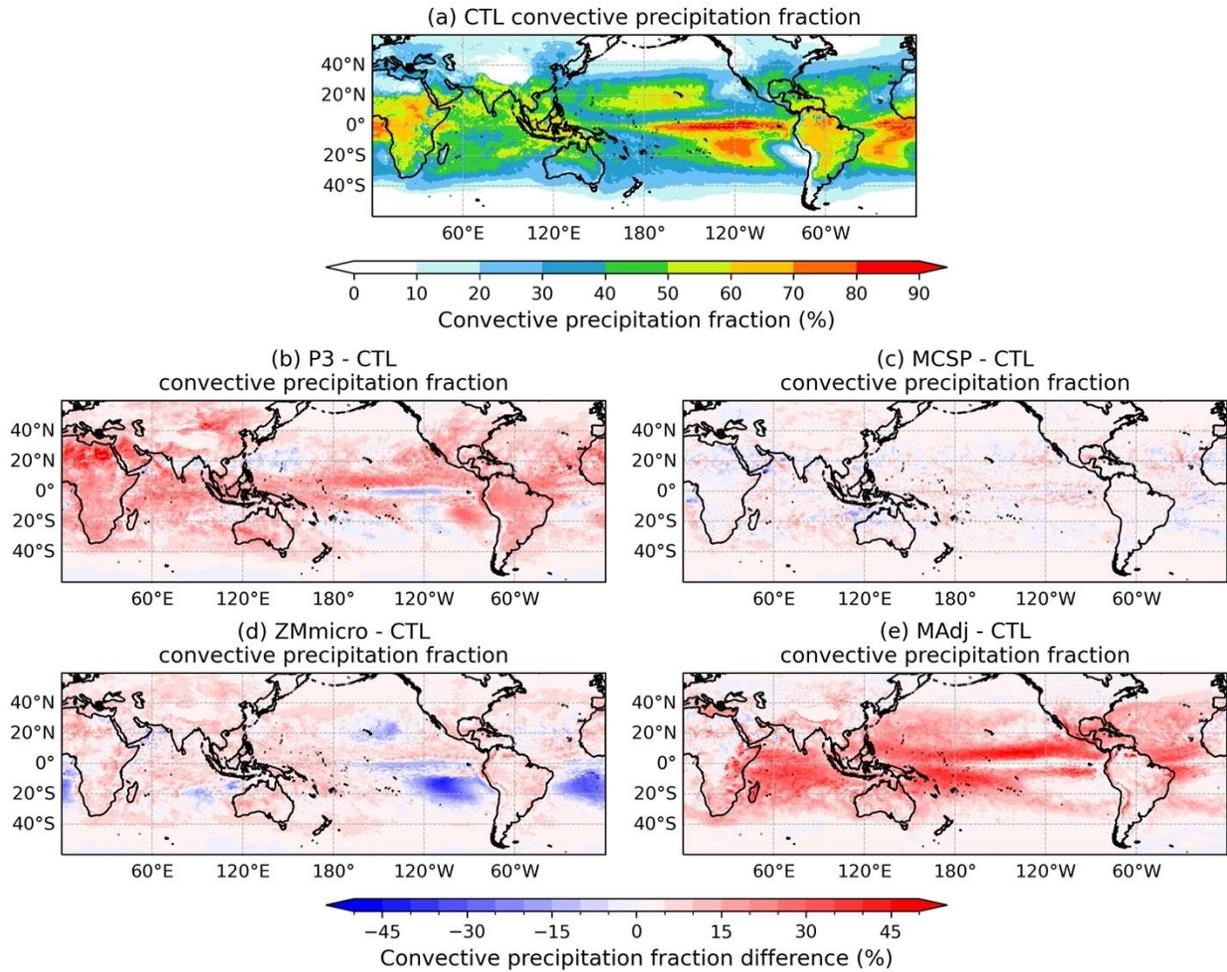

Figure 13. Maps of annual mean convective precipitation fraction in the default EAMv2 model (CTL) between 2005 and 2009, and the convective precipitation fraction difference (b-e) between individual new physics feature (i.e., P3 cloud microphysics, MCSP, convective microphysics scheme in ZM, and cloud base mass flux adjustment) and CTL simulations, respectively. Convective precipitation fraction is calculated as the contribution of hourly convective precipitation rate to total precipitation rate in the model.
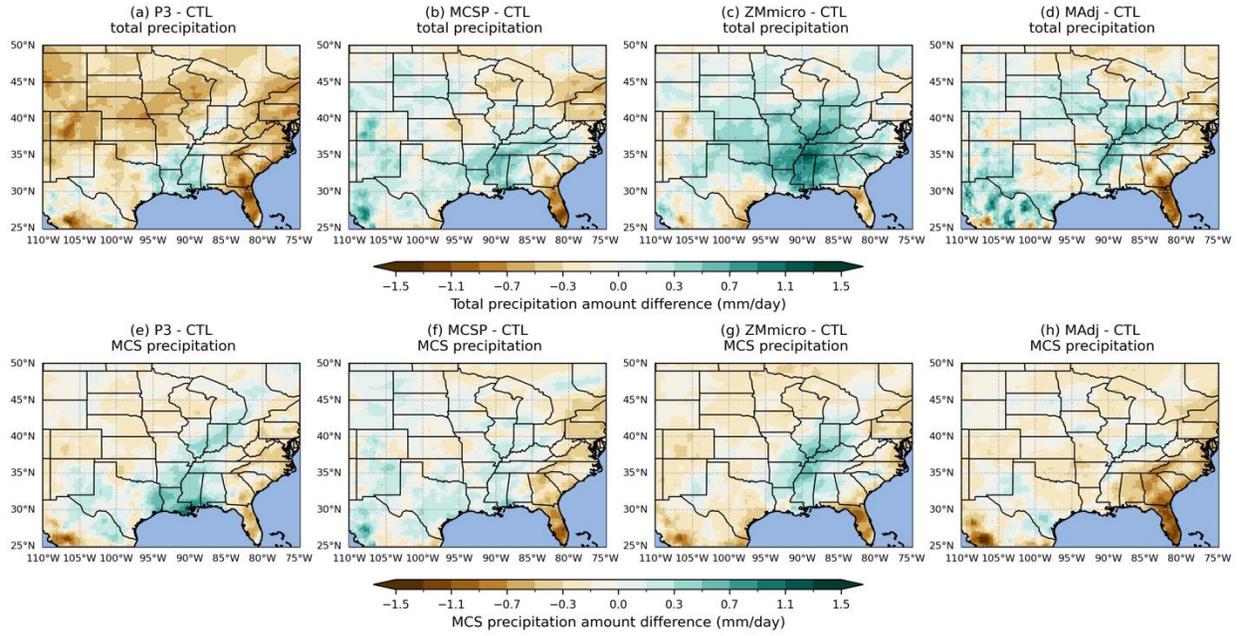

1252
1253
1254   Figure 14. Same as Figure 11, but for the CONUS region from March to August between 2005
1255   and 2009.
