8           **Key Points:**

- 9           • We introduce a framework to create 600-year ensembles of future weather and stream-  
10          flow for basins in the San Joaquin Valley.
- 11          • We discover vast variability and non-stationarity in flood and drought extremes  
12          in the region over the past 600 years.
- 13          • Variability in extremes is primarily attributed to natural variability, but climate  
14          changes are influential under longer planning horizons.

15 **Abstract**

16 To aid California’s water sector to better manage future climate extremes, we present  
 17 a method for creating a regional ensemble of plausible daily future climate and stream-  
 18 flow scenarios that represent natural climate variability captured in a network of tree-  
 19 ring chronologies, and then embed anthropogenic climate change trends within those sce-  
 20 narios. We use 600 years of paleo-reconstructed weather regimes to force a stochastic weather  
 21 generator, which we develop for five subbasins in the San Joaquin River in the Central  
 22 Valley region of California. To assess the compound effects of climate change, we cre-  
 23 ate temperature series that reflect scenarios of warming and precipitation series that are  
 24 scaled to reflect thermodynamically driven shifts in the daily precipitation distribution.  
 25 We then use these weather scenarios to force hydrologic models for each of the San Joaquin  
 26 subbasins. The paleo-forced streamflow scenarios highlight periods in the region’s past  
 27 that produce flood and drought extremes that surpass those in the modern record and  
 28 exhibit large non-stationarity through the reconstruction. Variance decomposition is em-  
 29 ployed to characterize the contribution of natural variability and climate change to vari-  
 30 ability in decision-relevant metrics related to floods and drought. Our results show that  
 31 a large portion of variability in individual subbasin and spatially compounding extreme  
 32 events can be attributed to natural variability, but that anthropogenic climate changes  
 33 become more influential at longer planning horizons. The joint importance of climate  
 34 change and natural variability in shaping extreme floods and droughts is critical to re-  
 35 silient water systems planning and management in the Central Valley region.

36 **Plain Language Summary**

37 California experiences cycles of floods and droughts that can be driven by both nat-  
 38 ural variability and climate change. The specific role of these drivers play in influenc-  
 39 ing extremes is uncertain, but can strongly dictate how to best plan and manage regional  
 40 water systems for future extremes. To better quantify the role of these drivers, we in-  
 41 troduce a framework that utilizes a 600-year tree-ring reconstruction to create long se-  
 42 quences of plausible ensembles of future weather and streamflow for key basins in the  
 43 San Joaquin Valley. We find that a large portion of variability in extremes can be at-  
 44 tributed to natural variability, but that anthropogenic climate changes become more in-  
 45 fluential at longer planning horizons. Furthermore, our perception of important drivers  
 46 can be skewed depending on the specific definitions used to analyze floods and droughts,

47 which can present significant challenges for adaptation planning and infrastructure de-  
48 velopment tied to hydroclimate indicators. This study also illustrates the vast variabil-  
49 ity in extremes that the region has experienced over the past 600 years and highlights  
50 the pitfalls of using stationary risk measures.

## 51 1 Introduction

52 The recent drought conditions impacting California are occurring within the broader  
53 context of two decades of extreme climate variability. Since 2000, California has expe-  
54 rienced four periods of drought: (2000-2003, 2007-2009, 2012-2016, and the ongoing drought  
55 beginning in the 2020). The former three complete drought periods were all ended by  
56 extreme atmospheric river (AR)-driven events. While offering much needed precipita-  
57 tion, these storms often cause widespread flooding and landslides. In 2017, extreme pre-  
58 cipitation associated with ARs generated California's wettest winter in a century and  
59 caused catastrophic damage to Oroville Dam, which prompted the evacuation of 188,000  
60 people and required nearly \$1 billion in repairs (Henn et al., 2020). Since this event, Cal-  
61 ifornia has ebbed and flowed through wet and dry periods, including experiencing the  
62 driest 22-year period in at least 1,200 years (A. P. Williams et al., 2022).

63 The recent two decades of California climate extremes are in part a manifestation  
64 of the extreme natural variability that characterizes the regional climate. Tree ring re-  
65 constructions have shown that the region experienced multiple persistent megadroughts  
66 over the past two millennia (late 800s, mid-1100s, late 1200s, mid-1400s, and late 1500s),  
67 long before anthropogenic influence (Stahle et al., 2000, 2007; A. Williams et al., 2021).  
68 Multi-millennial control runs of coupled global climate models (GCMs) have also repro-  
69 duced megadroughts in the Southwestern U.S. even without any external sea surface tem-  
70 perature (SST) forcing, suggesting that these droughts can develop due to internal cli-  
71 mate variability alone (Hunt, 2011). Some (but not all) of this natural drought variabil-  
72 ity is linked to major modes of atmospheric and oceanic variability, such as the El Niño  
73 Southern Oscillation (ENSO) and the Pacific Decadal Oscillation (PDO) (McCabe et  
74 al., 2004; Hoerling et al., 2009; Seager et al., 2015; Cook et al., 2016). Interspersed across  
75 the past two centuries, California has also experienced several extreme precipitation events  
76 (e.g., 1908-1909, 1913-1914, 1940-1941, 1955-1956, 1969, 1986, and 1997); most promi-  
77 nently the Great Flood of 1861-62 that turned the San Joaquin and Sacramento Valleys  
78 into an inland sea (M. D. Dettinger & Ingram, 2013). This event notably occurred af-

ter a 20-year drought (Null & Hulbert, 2007). Sediment reconstructions in the Klamath Basin suggest that the 1861-1862 megaflood was not an extreme outlier, but rather a 100-200-year event that has been matched in magnitude several times over the last two millennia (e.g., 212, 440, 603, 1029, 1300, 1418, 1605, 1750, and 1810 CE; M. D. Dettinger and Ingram (2013)).

The historic droughts and floods above, independent of anthropogenic-related warming, confirm the strong influence of natural climate variability in California and more broadly across the Western U.S. However, recent studies show that climate change is amplifying the severity of these extremes. Warming due to anthropogenic radiative forcing has intensified recent droughts in the region, primarily through enhanced atmospheric moisture demand and soil moisture depletion (A. P. Williams et al., 2020). As noted above, the recent cumulative drought conditions in California and the rest of the Western U.S. over the past two decades now ranks as the driest 22-year period in at least 1,200 years (A. P. Williams et al., 2022). Similarly, climate change is increasing the risk of extreme precipitation events via an increase in the strength of cool-season AR events associated with a rise in atmospheric moisture content (Kunkel, 2003; Kirchmeier-Young & Zhang, 2020). A recent study by X. Huang and Swain (2022) found that climate change has already doubled the likelihood of AR-driven megastorms similar to that which caused the Great Flood of 1861-62, and that megastorm sequences of increased frequency and larger magnitude are likely with continued warming.

Thus, the present and evolving risks posed by hydrologic extremes in California is defined by the combined influence of natural climate variability and anthropogenic climate change. Yet the degree to which these two factors will control the future frequency and magnitude of extremes remains uncertain (Hamlet & Lettenmaier, 2007; Siler et al., 2019; Bass et al., 2022). From the perspective of water resource decision-makers who are charged with planning and managing large-scale infrastructure to mitigate the impacts of extreme events, this ambiguity presents a significant challenge. If climate change is the dominant factor that will determine the future magnitude, frequency, and duration of extreme events, then resources and attention should be concentrated on identifying and narrowing the uncertainty of the most prominent climate change signals and propagating them into updated design event estimates used for planning. However, if natural variability plays an equal or larger role in determining the properties of hydrologic extremes relevant to engineering design, then research into the plausible range of extremes

112 due to natural variability should be equally prioritized (e.g., see Koutsoyiannis (2021)).  
113 A greater role of natural variability also suggests that dynamic and reversible adapta-  
114 tions may be favorable over irreversible investments. It is thus critically important to  
115 quantify the relative and joint roles of climate change versus natural variability in shap-  
116 ing the characteristics of hydrologic extremes, to help balance the allocation of atten-  
117 tion and resources in a way that best serves the water sector to prepare for future ex-  
118 treme events.

119 A growing body of work has sought to partition the relative effects of climate change  
120 and natural variability, with a focus on climate variables and in the context of multi-model  
121 ensemble simulations (Hawkins & Sutton, 2009; Yip et al., 2011; Knutti et al., 2017; Row-  
122 ell, 2012; Lehner et al., 2020). These studies primarily attribute variability in projected  
123 global and regional temperature and precipitation to climate change scenario uncertainty,  
124 global climate change model (GCM) uncertainty, and natural variability. Lehner et al.  
125 (2020) shows that scenario and model uncertainty are the dominant drivers of global decadal  
126 mean annual temperature and precipitation, but that natural variability dominates pro-  
127 jections of regional temperatures (in Southern Europe) and precipitation (in the U.S. Pa-  
128 cific Northwest and Sahel region), particularly at shorter (and more decision-relevant)  
129 time scales. Fewer studies have explicitly considered the role of natural climate variabil-  
130 ity when partitioning variance in projections of hydrologic and water systems variables  
131 (Kay et al., 2009; Jung et al., 2011; Vidal et al., 2015; Whateley & Brown, 2016; Schlef  
132 et al., 2018; Cai et al., 2021). Kay et al. (2009) found that flood frequency and winter-  
133 time runoff in Europe are mostly influenced by choice of GCM, although they quanti-  
134 fied natural climate variability using a limited number of GCM integrations with differ-  
135 ent initial conditions. Vidal et al. (2015) found that natural variability highly influences  
136 low flows in snow-dominated catchments in the French Alps, and Cai et al. (2021) found  
137 that natural variability is a dominant driver of rainy season runoff in Northeastern China.  
138 Jung et al. (2011) quantified natural variability using a block bootstrap on the histor-  
139 ical record and found it to have the largest impact on the variance of large floods, as com-  
140 pared to GCM structure, emission scenario, land use change scenario, and hydrologic model  
141 parameter uncertainty. Similarly, Whateley and Brown (2016) and Schlef et al. (2018)  
142 created ensembles of future streamflow projections with a stochastic weather generator  
143 and rainfall-runoff model and found that the variance of reservoir storage as well as wa-

144 ter system performance measures is mostly driven by natural climate variability, partic-  
145 ularly in the first few decades of the projections.

146 The relative roles of natural variability and climate change on the variance of hy-  
147 drologic variables of interest often depends on how natural variability is quantified and  
148 propagated into an ensemble of projections. In a majority of the climate studies (Hawkins  
149 & Sutton, 2009; Yip et al., 2011; Knutti et al., 2017; Rowell, 2012; Lehner et al., 2020)  
150 and three hydrologic studies (Kay et al., 2009; Jung et al., 2011; Vidal et al., 2015) ref-  
151 erenced above, natural variability was determined using multi-member ensembles of GCMs  
152 run with different initial conditions. However, the degree to which initial-condition en-  
153 sembles can represent true natural climate variability is unclear (Deser et al., 2020). For  
154 instance, these models poorly represent regional precipitation and drought persistence  
155 (Rocheta et al., 2014; Moon et al., 2018) and underestimate AR moisture flux and fre-  
156 quency (Zhou & Kim, 2018) all of which are important to regional planning and man-  
157 agement of water systems. While the recent generation of models in CMIP6 better rep-  
158 resents key features of natural climate variability (e.g., blocking; major climate modes)  
159 compared to older generations, significant biases remain (Tatebe et al., 2019; Schiemann  
160 et al., 2020)

161 An alternative way to estimate the relative influence of natural variability and cli-  
162 mate change on regional hydrologic response is through bottom-up approaches that em-  
163 ploy stochastically generated ensembles (Dessai & Hulme, 2004; Wilby & Dessai, 2010;  
164 Nazemi & Wheater, 2014). These methods require synthetic generators trained on ob-  
165 served weather or hydrologic records, which can generate large ensembles of scenarios  
166 that extrapolate beyond the observation limits of the historical record, maintain phys-  
167 ical plausibility, and embed climate changes into the ensemble. The generation and par-  
168 titioning of variability in the resulting hydroclimate metrics can provide a more robust  
169 way to quantify how much variance in regional hydrologic extremes is driven by climate  
170 changes versus natural variability. However, the availability of stochastic models to sup-  
171 port these analyses is limited, particularly when interested in the variance decomposi-  
172 tion of multiple properties of different hydrologic extremes (i.e., magnitude, duration,  
173 frequency, and spatial coherence of floods and droughts). Furthermore, the ways in which  
174 flood and drought events are defined, and particularly the time horizon (moving window)  
175 over which they are defined, can influence how the relative influences of climate variabil-  
176 ity and change are perceived. As time horizon shortens, it becomes increasingly difficult

177 to identify clear climate change signals amongst the noise of natural climate variability.  
178 For example, Lehner et al. (2020) attributed the vast majority of variance in winter pre-  
179 precipitation projections over the US Pacific Northwest to natural climate variability, but  
180 this was based on a 10-year moving window (i.e., decadal average). It is possible that  
181 any climate change impacts on mean winter precipitation, even if present, are not dis-  
182 cernable from the noise within such a short moving window. This issue is especially true  
183 for the properties of extreme events, because there are so few samples available from which  
184 to estimate signal from noise (even with many ensemble members). To date, it remains  
185 unclear how the choice of time horizon influences our understanding of the relative roles  
186 of natural climate variability and climate change on the uncertainty in hydrologic ex-  
187 tremes.

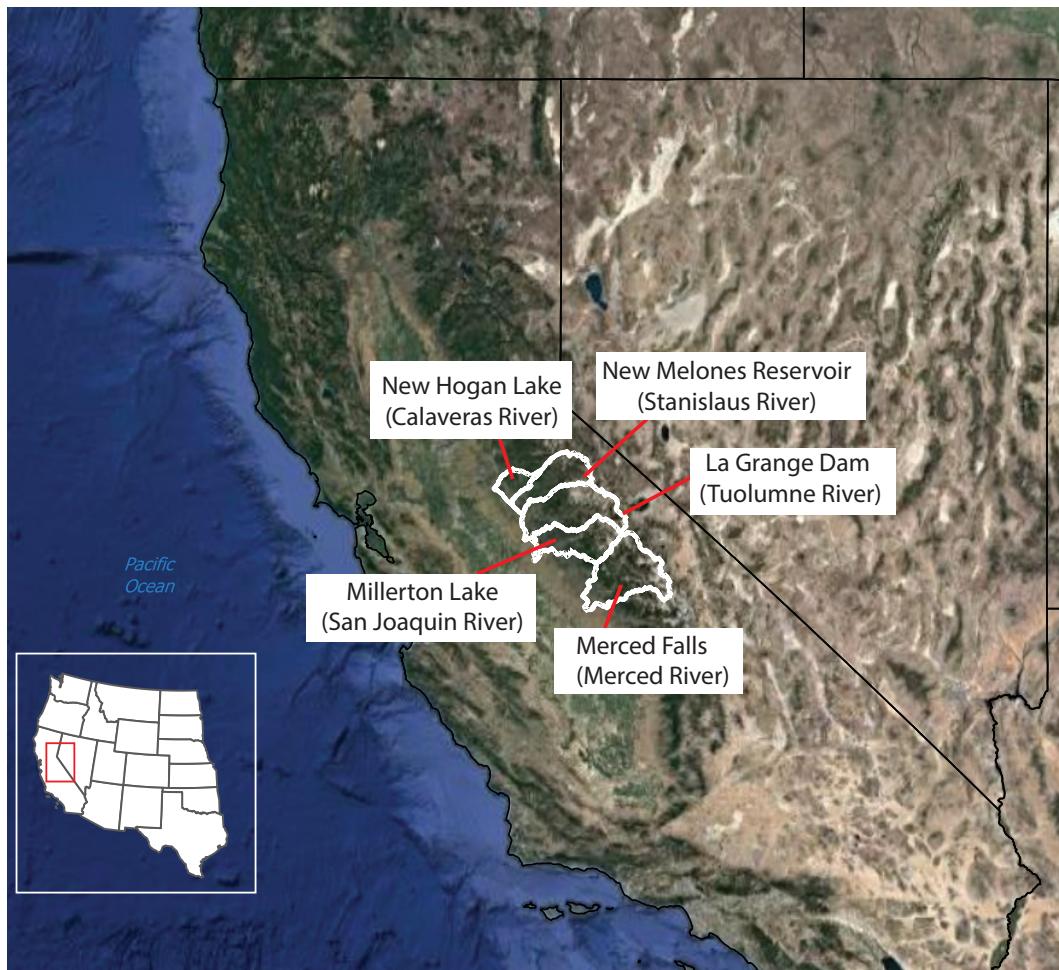

188 Based on the above knowledge gaps, this study addresses the following questions:

- 189 1. What is the relative importance of natural variability and climate change on vari-  
190 ability in decision-relevant drought and flood metrics for the Central Valley of Califor-  
191 nia?
- 192 2. How does the selected scale of the time horizon used for analyses influence the  
193 perceived importance of these drivers?

194 To answer these questions, we contribute a framework for creating a regionally con-  
195 sistent ensemble of plausible daily future climate and streamflow scenarios that repre-  
196 sent natural climate variability captured in a network of tree-ring chronologies, and then  
197 embed anthropogenic climate change trends within those scenarios. A key contribution  
198 of this study is the use of 600 years of paleo-informed weather regimes (WRs; Gupta et  
199 al. (2022)) to force a weather-regime based stochastic generator (Steinschneider et al.,  
200 2019; Najibi et al., 2021), which we develop for five watersheds in the San Joaquin River  
201 basin. To assess the compound effect of climate change, we create temperature series that  
202 reflect projected scenarios of warming and precipitation series that have been scaled to  
203 reflect thermodynamically driven shifts in the distribution of daily precipitation. We then  
204 use these weather scenarios to force hydrologic models for each basin, generating ensem-  
205 bles of streamflow across the region. Decision relevant hydrologic metrics for character-  
206 izing flood and drought conditions are defined and calculated across San Joaquin sub-  
207 basins and across the paleo-period using time horizons of varying scale (see Appendix  
208 B). Variance decomposition is then employed to characterize the relative contributions

209 of natural variability and climate changes as drivers of flood and drought hazards in in-  
 210 dividual subbasins and for spatially compounding extremes that emerge across groups  
 211 of subbasins.

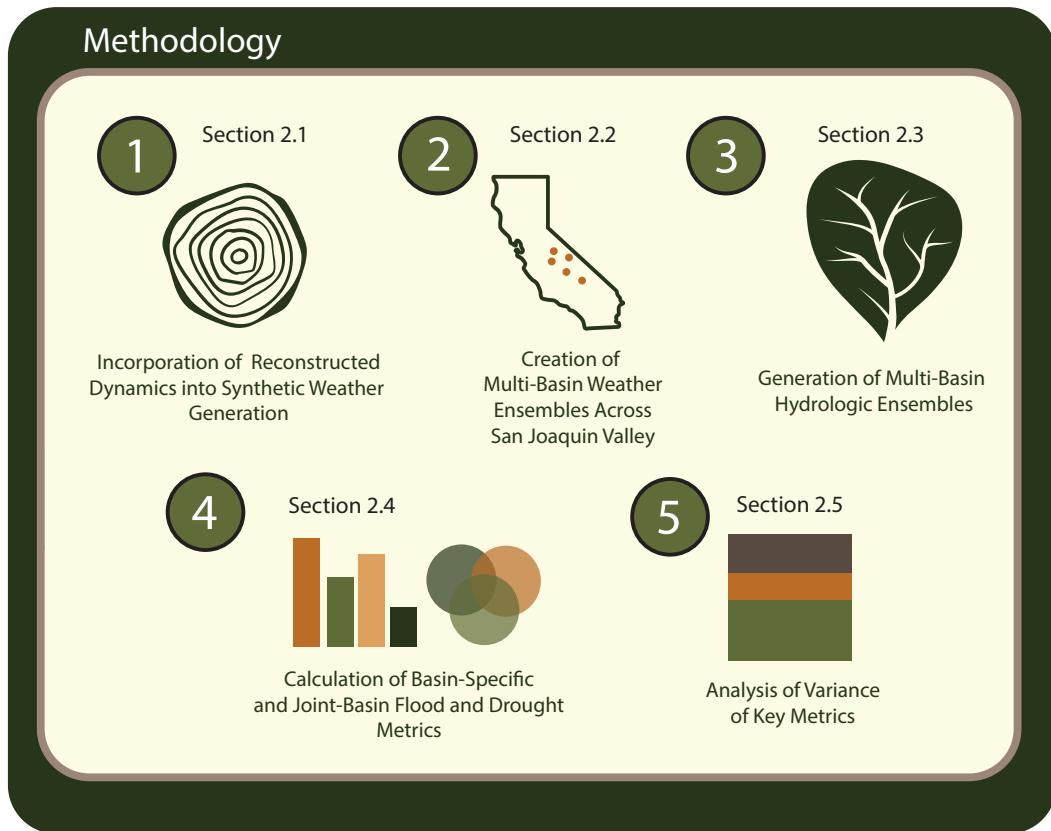

212 **2 Data and Methods**

**Figure 1.** The study area is comprised of five subbasins within the greater San Joaquin River basin.

213 This study focuses on five subbasins within the San Joaquin River basin (Figure  
 214 1): the Tuolumne River, the Merced River, the San Joaquin River, the Stanislaus River,  
 215 and the Calaveras River. The ultimate goal of this study is to partition the effects of nat-  
 216 ural climate variability and climate change on different properties of floods and droughts  
 217 across these watersheds. We contribute a five-step methodology in order to achieve this  
 218 goal (Figure 2). We first create a novel method to incorporate reconstructed weather regime

<sup>219</sup> dynamics (Gupta et al. 2022) into the generation of daily weather through the paleo-  
<sup>220</sup> period (Section 2.1). Then, we create 600 years of surface weather ensembles across the  
<sup>221</sup> five subbasins of the San Joaquin conditioned upon these reconstructed dynamics. We  
<sup>222</sup> also create additional ensembles of surface weather layered with thermodynamic climate  
<sup>223</sup> changes, such as temperature trends and precipitation scaling (Section 2.2).

**Figure 2.** The main methodological components of this study. Reconstructed weather regime dynamics are used to drive weather simulations across the San Joaquin valley that also embed signals of thermodynamic climate change. Ensembles of generated surface weather are used to force hydrologic models to develop streamflow ensembles. Metrics pertaining to flood and drought extremes are calculated throughout the simulation period across basins and ensemble members, and an ANOVA decomposition is used to partition the variance of each metric across the ensemble into variance contributions from thermodynamic climate changes and natural variability.

<sup>224</sup> These ensembles are forced through hydrologic models (SAC-SMA and HYMOD)  
<sup>225</sup> calibrated for each subbasin to generate ensembles of daily streamflow (Section 2.3). From

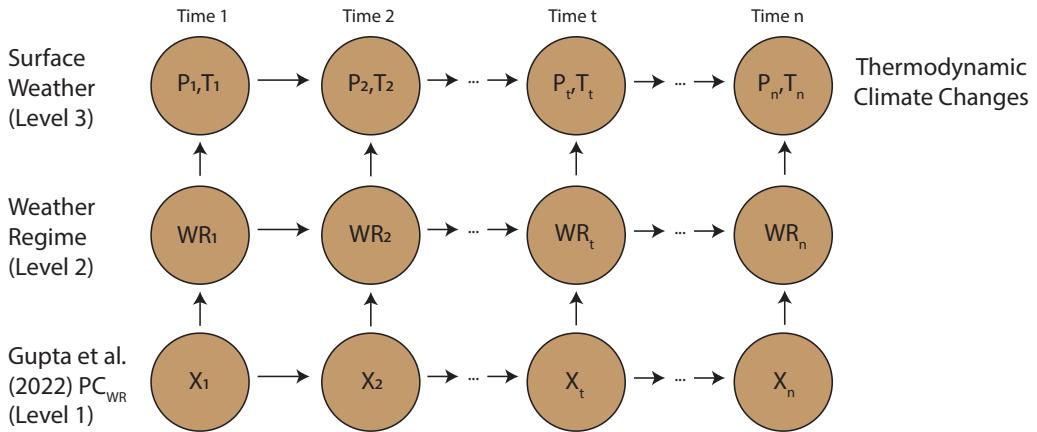

these streamflow ensembles, we calculate flood and drought metrics, including copula-based metrics to quantify joint flood hazard across basins (Section 2.4). Finally, analysis of variance (ANOVA) is used to partition the contribution of natural variability and the imposed climate changes to variability in the different flood and drought metrics considered (Section 2.5).

## 2.1 Reconstruction of WR Dynamics

Ensembles of plausible future climate are generated using our extensions of the WR-based stochastic weather generator presented in Steinschneider et al. (2019) and Najibi et al. (2021) to incorporate paleo-reconstructions of WRs. The generator is comprised of a three-step hierarchical structure (Figure 3): (1) identification and simulation of WRs that define large-scale patterns of atmospheric flow across the entire Western U.S., (2) simulation of local weather conditioned on the WRs, and (3) perturbations to the simulated weather reflective of thermodynamic climate change. This study extends step (1) to utilize reconstructed WRs created in Gupta et al. (2022). In that study, a multi-objective optimization and regression-based framework was used to reconstruct the annual frequency of five dominant Western U.S. weather regimes back to 1400 CE based on a gridded, tree-ring based reconstruction of cold season precipitation developed by A. P. Williams et al. (2020) and extended in Borkotoky et al. (2021). Specifically, the first four principal components of annual weather regime occurrence were reconstructed (termed  $PC_{WR}$  in Gupta et al. (2022)), which effectively contained all of the information on the annual frequencies of the five WRs. In this study, these principal components are used to force a non-homogeneous hidden Markov model (NHMM), whereby WR states are modeled as a first-order Markov chain with a non-stationary transition probability matrix conditioned on the reconstructed  $PC_{WR}$  from Gupta et al. (2022). The NHMM is fit to the first nine principal components of daily 500 hPa geopotential height from NOAA-CIRES-DOE Twentieth Century Reanalysis (V3) dataset (Slivinski et al., 2019) between 180-100°W and 30-60°N (i.e., the Pacific/North American sector) from 1950-2017. The NHMM is forced with the four reconstructed principal components ( $PC_{WR}$ ) that overlap the same time period, defining a time-varying transition probability matrix shown in Equation 1:

$$P(WR_t = i | WR_t = j, \mathbf{X}_t = \mathbf{x}) = \frac{\exp(\beta_{0j,i} + \boldsymbol{\beta}'_{j,i} \mathbf{x})}{\sum_{k=1}^K \exp(\beta_{0j,i} + \boldsymbol{\beta}'_{j,i} \mathbf{x})} \quad (1)$$

255 Here, the transition probability from WR  $i$  to WR  $j$  at time  $t$  is conditioned on  $\mathbf{X}'_t =$   
 256  $[PC_{WR_{1,t}}, PC_{WR_{2,t}}, PC_{WR_{3,t}}, PC_{WR_{4,t}}]$  a vector of daily covariates developed by repeat-  
 257 ing the annual values of each for each day of the year. These covariates (Level 1 in Fig-  
 258 ure 3) are used within a multinomial logistic regression with intercepts  $\beta_{0j,i}$  and coef-  
 259 ficients  $\beta_{j,i}$  to define the transition probabilities, with a prime denoting the vector trans-  
 260 pose. The fitted multinomial regression can be used to estimate the time-varying tran-  
 261 sition probabilities and simulate WRs across the entire 600-year period over which re-  
 262 constructed values of  $PC_{WR}$  are available. More information on the NHMM can be found  
 263 in Section S1. We use this method to create a 50-member ensemble of daily, 600-year  
 264 weather regime time series (Level 2 in Figure 3; convergence plots of corresponding stream-  
 265 flow available in Figure S1).

**Figure 3.** Flow chart of the main components of the weather generator. Boundary forcing variables (here the  $PC_{WR}$  from Gupta et al. (2022)) influence the evolution of the discrete weather regime time series. Surface weather is then conditioned upon the weather regime time series. Thermodynamic climate changes (temperature increases and precipitation-temperature scaling) are applied to the surface weather post-generation.

## 266 2.2 Generation of Local Surface Weather Conditioned on WRs

267 Time series of daily surface weather are generated based on the simulated time se-  
 268 ries of WRs (Level 3 in Figure 3). Here, observed daily precipitation, minimum, and max-  
 269 imum temperature are taken from the 1/16° resolution gridded meteorological dataset  
 270 of Livneh et al. (2015) for water years (WY) 1950-2013. These historical weather data

are block bootstrapped based on the sequence of simulated WRs to create new sequences of weather. For example, if the NHMM simulates a sequence of  $n$  consecutive days in WR  $i$ , an  $n$ -sized block of surface weather is resampled from the historical period that is also in WR  $i$  and that meets two other criteria: (1) the chosen historical block falls into a two-week window around the simulated day of the year; and (2) the day prior to the historical block is in the same precipitation state as the simulated day (wet or dry). The weather generator is run simultaneously across the five basins to create internally consistent (i.e., spatially correlated) weather across the region. Given their large synoptic scale, we use the occurrence of an atmospheric river (taken from Gershunov et al. (2017)) to represent a common precipitation state across basins. The process is repeated for each ensemble until a full sequence of 600 years of daily minimum and maximum temperature and precipitation has been generated.

Thermodynamic changes, in the form of shifts in temperature and precipitation scaling with warming, are imposed after surface weather is generated. Step changes in temperature between 0–4°C are added to each grid cell's simulated temperature. Quantile mapping is used to scale the precipitation distribution with warming, whereby the upper tail (99.9<sup>th</sup> percentile) of the non-zero precipitation distribution is made more intense, the lower tail of non-zero precipitation is suppressed downward, but the mean of daily precipitation is left unchanged. This scaling reflects an intensification of the precipitation regime and is consistent with GCM-based projections of future precipitation in California (Michaelis et al., 2022). We consider 5 different scaling rates equivalent to  $0X$  (0%  $^{\circ}C^{-1}$ ),  $0.5X$  (3.5%  $^{\circ}C^{-1}$ ),  $1X$  (7%  $^{\circ}C^{-1}$ ),  $1.5X$  (10.5%  $^{\circ}C^{-1}$ ), and  $2X$  (14%  $^{\circ}C^{-1}$ ) the Clausius-Clapeyron (CC) scaling rate, which dictates how the moisture holding capacity of the atmosphere scales with warming. That is, the 99.9th percentile of non-zero precipitation is scaled up by either 0%  $^{\circ}C^{-1}$ , 3.5%  $^{\circ}C^{-1}$ , 7%  $^{\circ}C^{-1}$ , 10.5%  $^{\circ}C^{-1}$ , or 14%  $^{\circ}C^{-1}$ , while the lower body of the distribution is scaled down accordingly to maintain the same distribution mean. The range of selected scaling rates are derived from observational and model-based studies that most often indicate extreme precipitation-temperature scaling at the  $1X$  CC rate, but occasionally suggest the possibility for sub-CC ( $0X$ ,  $0.5X$ ) or super-CC ( $1.5X$ ,  $2X$ ) scaling rates due to interactive effects between enhanced specific humidity and storm dynamics (Wasko et al., 2018; Martinkova & Kyseley, 2020; Ali et al., 2022; Michaelis et al., 2022; Sun & Wang, 2022).

These scaling rates are combined with the different scenarios of warming, so that precipitation scaling is tied to the imposed temperature scenario and respects the thermodynamic mechanism that drives precipitation change. We consider five scenarios of warming, including 0°C, 1°C, 2°C, 3°C, and 4°C above the climatological average. This range of warming was inferred from an ensemble of CMIP6 mid-century (2015-2050) projections over central California under the SSP2-4.5 scenario, taken from CarbonPlan (see Figure S2; Chegwidden et al. (2022)). All together, we develop 25 different scenarios of climate change (5 temperature scenarios and 5 scaling scenarios), with each scenario containing 50 ensemble members (i.e., 50 stochastic 600-year time series of precipitation and temperature), in addition to a baseline ensemble with no changes imposed. Technical details on the quantile mapping procedure, and other details of the stochastic weather generator, are provided in Steinschneider et al. (2019) and Najibi et al. (2021).

### 2.3 Generation of Regional Streamflow Through Process-Based Hydrologic Models

Surface weather ensembles are used to simulate daily streamflow ensembles at the mouth of each of the five San Joaquin subbasins using the Sacramento Soil and Moisture Accounting Model (SAC-SMA) (Burnash et al., 1995) coupled with a SNOW-17 model (Anderson, 1976). The models, documented in Wi and Steinschneider (2022), are spatially distributed and utilize a Lohmann routing model Lohmann et al. (1998) to trace runoff from hydrologic response units (HRUs) through each river channel. The SAC-SMA models are calibrated using a pooled calibration approach (Wi et al., 2015) based on the average Nash Sutcliffe Efficiency (NSE) across the five subbasins simultaneously. Calibration and evaluation was based on historical Full Natural Flows (FNF) between WY 1989-2013, acquired from California Data Exchange Center (CDEC) FNF stations that lie within each subbasin: Tuolumne River at La Grange Dam (TLG), Friant Dam on Miller-ton Lake (MIL), Merced River near Merced Falls (MRC), New Hogan Lake (NHG), and New Melones Reservoir (NML) (G. Huang & Kadir, 2016). The models are calibrated over WY 1989-2003 and then evaluated across WY 2004-2013.

To verify that our streamflow extremes and variance decomposition results are not strongly dependent on the selection of the SAC-SMA model, we also employ the HYMOD conceptual hydrologic model (HYMOD; (Moore, 2007)) specifically in the Tuolumne Basin. Our primary results will be presented using the SAC-SMA model but more de-

335 tailed analysis of how hydrologic model selection impacts the estimates of flood and drought  
 336 metrics as well as their partitioning of variance is provided in Section S2. More infor-  
 337 mation about the calibration process and parameter values for all hydrologic models can  
 338 be found in Wi and Steinschneider (2022).

339 **2.4 Metrics of Hydrologic Extremes**

340 A series of flood and drought metrics, described below, are calculated for each en-  
 341 semble member and each climate scenario and across two time horizons: 30 and 100 years.  
 342 As stated in the latest update to the Central Valley Flood Protection Plan (CVFPP),  
 343 the state of California is actively prioritizing investments in flood management over a  
 344 30-year planning horizon (California Department of Water Resources, 2022). A 100-year  
 345 planning horizon is not actively used in the CVFPP, but it represents a time scale rel-  
 346 evant to longer term major infrastructure investments. Further, it allows the exploration  
 347 of the longer climate time horizon drivers. We partition the variance of each metric be-  
 348 tween the drivers of climate change and natural climate variability using the ensemble  
 349 of scenarios described above. Appendix A contains a glossary with commonly used terms  
 350 that are referred to through the methods. Appendix B contains a summarized list of all  
 351 of the flood and drought metrics used in this study, including their decision relevance.

352 **2.4.1 Flood Metrics**

353 Flows associated with a 10-year and 100-year return period are used as flood met-  
 354 rics in this study. The 100-year floodplain currently drives larger riverine infrastructure  
 355 development and flood risk management in California (California Department of Wa-  
 356 ter Resources, 2022). Though not as common for current planning and management in  
 357 California, the 10-year return period flow captures risk to smaller floodplains and drives  
 358 smaller investments (California Department of Water Resources, 2006). The decadal and  
 359 centennial flood are estimated by fitting a generalized extreme value (GEV) distribution  
 360 to the three-day annual maxima at each CDEC gauged location in the five subbasins.  
 361 The three-day flood was chosen because it a common metric used in flood risk assess-  
 362 ments in California (California Department of Water Resources, 2006; Chung, 2009; Brekke  
 363 et al., 2009; Maurer, Brekke, & Pruitt, 2010; Maurer, Hidalgo, et al., 2010), and because  
 364 it better captures the concurrence of flooding across multiple basins (described further

365 in section 2.4.3). For each ensemble member, we fit the GEV distribution for the whole  
 366 600-year paleo-period as well as across smaller 30-year and 100-year moving windows.

367 ***2.4.2 Drought Metrics***

368 There is no state statutory definition of drought since it can be classified differently  
 369 across impacted sectors and stakeholders. Historical hydrologic droughts have been tra-  
 370 ditionally identified based on a combination of metrics that capture the magnitude and  
 371 duration of water deficit at key reservoirs (California Department of Water Resources,  
 372 2015). Since we develop metrics for gauged locations near these reservoirs, we opt to use  
 373 a more generalized Standardized Streamflow Index (SSI) to quantify hydrologic drought  
 374 (Vicente-Serrano et al., 2012). To calculate the SSI, daily simulated flows are first ag-  
 375 gregated to a monthly time step. We then use a flexible non-parametric empirical method  
 376 to estimate non-exceedance probabilities using the Gringorten plotting position (see Farahmand  
 377 and AghaKouchak (2015)). To create the SSI, the associated non-exceedance probabili-  
 378 ties are passed through the quantile function of the standard normal distribution, re-  
 379 sulting in a series with an assumed mean of zero and standard deviation of one. We then  
 380 use the SSI index to define three drought metrics, following McKee et al. (1993):

381 1. Drought Occurrence: The number of months characterized by an SSI value less  
 382 than -1, divided by the total months in the window over which the metric was calculated.  
 383 An SSI value of less than -1 captures moderate to severe drought hazard.

384 2. Drought Intensity: The minimum SSI value in the moving window.

385 3. Drought Duration: The maximum number of consecutive months with an SSI  
 386 below -1.5 in the moving window. An SSI value of less than -1.5 captures severe drought  
 387 hazard.

388 The SSI index is calculated for each ensemble member and climate change scenario,  
 389 and the metrics are reported across 30-year and 100-year moving windows.

390 ***2.4.3 Copula-Based Flooding Metrics***

391 The San Joaquin basin is a key component in the state's comprehensive water de-  
 392 livery system, and a levee breach due to compounding flooding across subbasins in the  
 393 region could disrupt deliveries of irrigation water to 3 million acres of farmland in the

394 Central Valley (Taylor, 2017). Thus, we develop a spatially-compounding flood metric  
 395 to capture this hazard. As discussed in Zscheischler et al. (2020), spatially compounding  
 396 flood hazard can be characterized using an n-dimensional Gaussian copula that de-  
 397 fines a metric of joint flood hazard across n basins simultaneously. Let  $x_{t,1}, \dots, x_{t,n}$  be  
 398 the annual maxima of 3-day mean streamflow in each of the n basins in year  $t$ . We first  
 399 fit GEV distributions to the individual three-day annual maxima for each basin ( $i =$   
 400  $1, \dots, n$ ). The three-day annual maxima in each year  $t$  are then transformed to be uni-  
 401 form pseudo-observations,  $u_{t,i} = F_{GEV}^{-1}(x_{t,i})$ , where  $F_{GEV}^{-1}$  is the inverse cdf of the fit-  
 402 ted GEV distribution for basin  $i$ . These pseudo-observations are used to evaluate the  
 403 joint CDF of the flood data based on a Gaussian copula:

$$C(u_{t,1}, \dots, u_{t,n}) = P(U_1 \leq u_{t,1}, \dots, U_n \leq u_{t,n}) = \Phi_n(\phi^{-1}(u_{t,1}), \dots, (\phi^{-1}(u_{t,n})|\Sigma) \quad (2)$$

404 Here,  $\phi^{-1}$  is the inverse CDF of the standard normal distribution and  $\Phi_n(\cdot|\Sigma)$  is  
 405 the multivariate normal CDF with zero mean and correlation matrix  $\Sigma$ , which is set equal  
 406 to the Spearman rank correlation matrix for three-day annual maxima across basins. Us-  
 407 ing the fitted copula, we can then calculate the joint probability that multiple subbasins  
 408 experience flooding above some threshold. For example, consider two subbasins with 100-  
 409 year flood magnitudes of  $x_1$  and  $x_2$ , respectively, inferred from their fitted (GEV) marginal  
 410 distributions. Then, the probability that both subbasins simultaneously experience floods  
 411 that exceed the 100-year flood is equal to (Zhang & Singh, 2019):

$$P(X_1 > x_1, X_2 > x_2) = 1 - P(X_1 \leq x_1) - P(X_2 \leq x_2) + P_{1,2}(X_1 \leq x_1, X_2 \leq x_2) = \\ 1 - F_{GEV1}(x_1) - F_{GEV2}(x_2) + \Phi_n(\phi^{-1}(F_{GEV1}(x_1)), \phi^{-1}(F_{GEV2}(x_2))|\Sigma) \quad (3)$$

412 Similar calculations are available to evaluate the probability that three or more basins  
 413 experience flooding above set thresholds. These probabilities can be used directly as a  
 414 metric of joint flood hazard, and we can partition the variance of this metric between  
 415 climate changes and natural variability across our ensemble and for 30-year and 100-year  
 416 moving windows.

417      **2.5 Analysis of Variance in Hydrologic Metrics**

418      We use an ANOVA to partition the variance in the hydrologic flood and drought  
 419      metrics above into components attributable to different sources of variation. A two-way  
 420      ANOVA was used to determine the uncertainty in hydrologic metrics attributable to un-  
 421      certainty in temperature change ( $T$ ), precipitation scaling rate ( $P$ ), their interactions,  
 422      and uncertainty in metrics attributable to natural variability. The temperature change  
 423      factor has  $i = 1, \dots, 5$  levels (0, 1, 2, 3, 4 °C), and precipitation scaling factor has  $j=1,\dots,5$   
 424      levels (0%, 3.5%, 7%, 10.5%, 14% per °C). For each combination of levels, there are 50  
 425      stochastic realizations of the metric of interest. The linear model on which the ANOVA  
 426      is based is given as:

$$x(i, j, s) = \mu + \alpha(i) + \beta(j) + \gamma(i, j)^{TP} + \varepsilon(i, j, s) \quad (4)$$

427      Where  $x(i, j, s)$  is the hydrologic metric for a given level  $i$  and  $j$  of factors  $T$  and  
 428       $P$ , respectively, and a given ensemble member  $s$ . The grand mean for the metric  $x$  across  
 429      the entire ensemble is  $\mu$ ;  $\alpha(i)$  equals the average deviation in  $x$  from  $\mu$  for ensemble mem-  
 430      bers with temperature changes at level  $i$ ;  $\beta(j)$  equals the average deviation in  $x$  from  $\mu$   
 431      for ensemble members with precipitation scaling rate at level  $j$ ;  $\gamma(i, j)^{TP}$  is the inter-  
 432      action term between temperature change and precipitation scaling; and  $\varepsilon(i, j, s)$  is the  
 433      error term, which is used here to represent natural variability in the metric not explained  
 434      by the different climate change factors. The total sum of squares  $SS_{total}$  expresses the  
 435      total variation in the hydrologic metric  $x$ , and is comprised of the sum of variation at-  
 436      tributable to temperature change ( $SS_T$ ), precipitation scaling rate ( $SS_P$ ), their inter-  
 437      action ( $SS_{Int}$ ), and natural variability ( $SS_\varepsilon$ ):

$$SS_{total} = SS_T + SS_P + SS_{Int} + SS_\varepsilon \quad (5)$$

438      The fraction of variance attributable to each source is calculated by dividing each  
 439      component by  $SS_{total}$ . This fraction of attributable variance is calculated separately in  
 440      30-year and 100-year rolling windows for each of the metrics above.

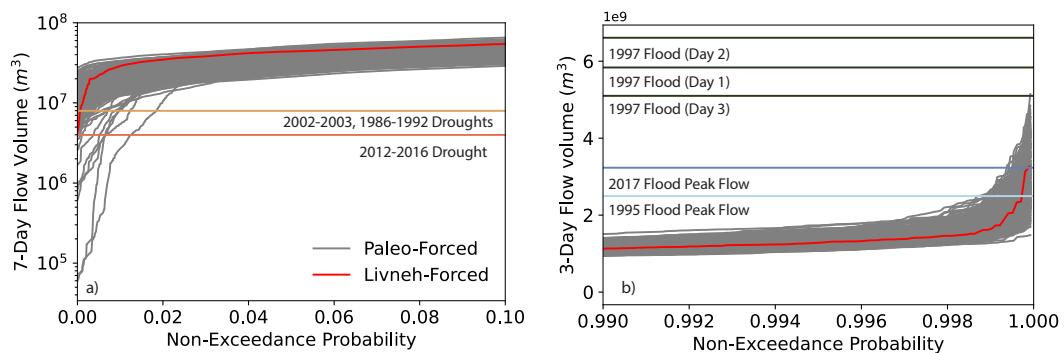

441     **3 Results**

442     The results of this work are presented as follows. First, Section 3.1 shows a com-  
 443     parison of the variability in the paleo-informed streamflow with events from the avail-  
 444     able observed historical record. Then, Section 3.2 shows the flood and drought extremes  
 445     reconstructed for the baseline scenario (i.e., influence of natural variability alone). Sec-  
 446     tion 3.3 demonstrates how the imposed climate changes affect those extremes. Section  
 447     3.4 demonstrates the variance partitioning of extremes across climate change and nat-  
 448     ural variability. A more detailed evaluation of the stochastic weather generator's per-  
 449     formance is presented in the Supporting Information (see Figures S3-S7), which demon-  
 450     strates how well the generator captures characteristics of precipitation and minimum and  
 451     maximum temperature.

452     **3.1 Paleo-Informed Streamflow Characteristics**

453     Figure 4 demonstrates the broader variability that is attained in the streamflow  
 454     ensembles when SAC-SMA is forced with paleo-reconstructed weather at the Don Pe-  
 455     dro gauge in the Tuolumne Basin. Figure 4a focuses on 7-day flows and the lower tail  
 456     of the distribution and Figure 4b zooms in on the upper tail distribution of 3-day flows.  
 457     Each grey line represents sorted flow volumes across 30-year chunks of the paleo-reconstruction  
 458     across all 50 ensemble members. These volumes are compared with those that come from  
 459     forcing the generator over the modern period (1987-2013) with historical Livneh precip-  
 460     itation and temperature data (red line). Key events from the observed record are an-  
 461     notated as colored horizontal lines. Overall, the paleo-informed streamflow envelopes and  
 462     expands upon the historical SAC-SMA model flows by creating instances of wetter 3-  
 463     day flows and drier 7-day flows. Furthermore, the paleo-ensemble is characterized by drier  
 464     events than key drought periods from the observed record as demonstrated in Figure 4a.  
 465     The generator is unable to create 3-day flows that reach the peak of the 1997 New Year's  
 466     flood period due to underestimation of precipitation associated with this storm that is  
 467     a known error in the Livneh dataset (Pierce et al., 2021). In turn, models conditioned  
 468     on the Livneh dataset tend to underestimate the flows associated with this event. How-  
 469     ever, the inclusion of the paleo-reconstruction allows the generator to create flows that  
 470     far surpass the magnitude of peak flows associated with the 1995 and 2017 floods. Over-  
 471     all, the expanded envelope of daily scale streamflows enabled by the paleo-reconstruction  
 472     provide rich context for exploring plausible flood and drought extremes in the Tuolumne

473 Basin. Figure S9 demonstrates similar results for the rest of the San Joaquin River basins,  
 474 particularly in capturing drought dynamics. The generator conditioned on the Livneh  
 475 dataset suffers from the same difficulty of capturing the 1997 flood peak flows; however,  
 476 in some basins like Merced and Millerton, the paleo-conditioned generator provides ex-  
 477 tended variability that can help overcome these limitations (Figures S9b,d). New Hogan  
 478 Lake is the only gauged location in which the Livneh-conditioned model can capture the  
 479 1997 flood peak flows, but this is primarily because the associated peak flows were not  
 480 as extreme in this region relative to other notable flooding events. Of the five basins, cap-  
 481 turing dynamics in the Tuolumne is the most challenging; it is also representative of high-  
 482 elevation basins that exhibit rich snow dynamics. Thus, we proceed through the rest of  
 483 the results with a focus on the Tuolumne Basin, though corresponding figures for the rest  
 484 of the basins can be found in the supplement. Section 3.2 further elaborates on the value  
 485 of the paleo-forced generator and its representation of key flood and drought metrics through  
 486 the reconstruction.

**Figure 4.** a) 7-day and b) 3-day flow volumes at the Don Pedro gauge in the Tuolumne Basin derived from the paleo-informed streamflow ensembles compared to the Livneh-forced generator over the modern period. Key events from the observed record are shown as colored lines. Each grey line represents sorted volumes for each year in 30-year chunks of the paleo-reconstruction across all 50 ensemble members.

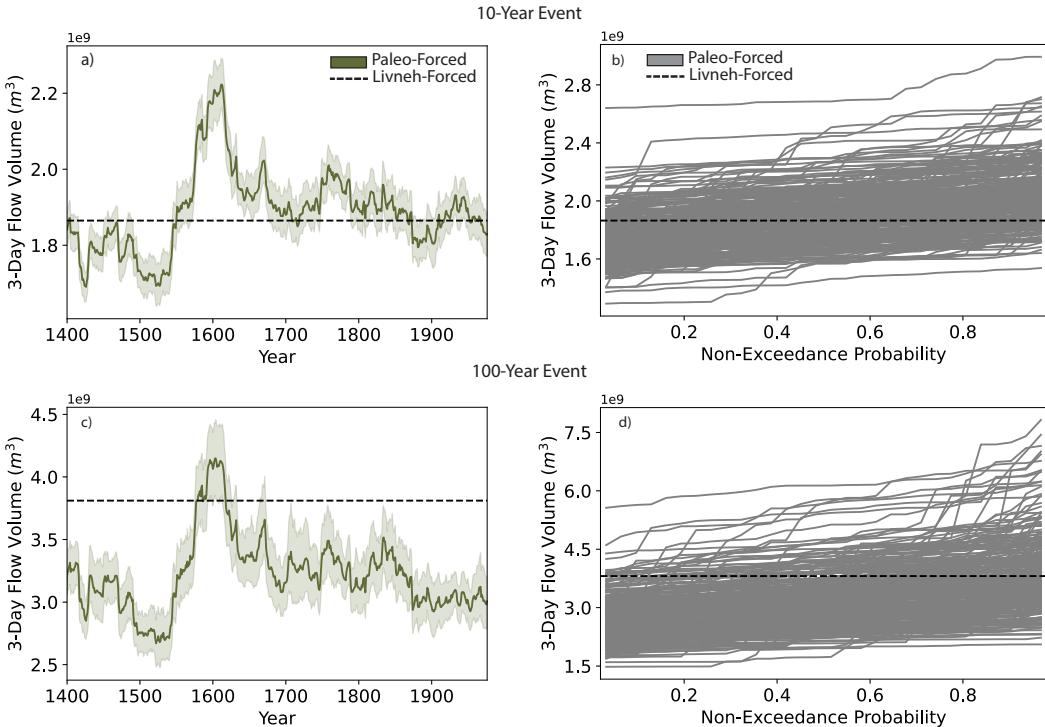

### 487 3.2 Reconstruction of Natural Variability in Extremes

#### 488 3.2.1 Individual Basin Flood Hazards

489 The individual Tuolumne subbasin flood hazard is quantified based on the 10-year  
 490 and 100-year flood events associated with 3-day annual maximum flows, calculated us-

491 ing a GEV distribution fit to 3-day maxima in each basin and with two moving windows  
492 of length 30 and 100 years. Figures 5a and 5c show these return levels at the Don Pe-  
493 dro gauge in the Tuolumne Basin using a 30-year moving window. The return levels are  
494 calculated for all ensemble members of the baseline generator, where the solid line rep-  
495 presents the mean return level across the ensemble members and the shading represents  
496 the 5<sup>th</sup>/95<sup>th</sup> percentiles. Figures 5b and 5d are non-exceedance plots of the three-day  
497 annual maxima across the extent of the paleo-reconstruction ensemble. The dashed black  
498 line represents the three-day annual maxima associated with the 10-year and 100-year  
499 return period events as derived from the SAC-SMA model forced with Livneh histori-  
500 cal precipitation and temperature that overlaps with the observed record (1987-2013).  
501 In order to facilitate the most equivalent comparison between the two datasets, each gray  
502 line represents the sorted three-day annual maxima volumes over sets of 30-year segments  
503 of the paleo-reconstruction and across all 50 ensemble members.

504 The return levels in Figures 5a,c both show clear peaks centered around 1600 CE,  
505 which highlights a prominent pluvial period in the region's past hydroclimate. This plu-  
506 vial is represented in the original WR reconstruction from Gupta et al. (2022) and broadly  
507 confirmed by other reconstructions (D'Arrigo & Jacoby, 1991; Schimmelmann et al., 1998;  
508 Stahle et al., 2007; M. D. Dettinger & Ingram, 2013). M. D. Dettinger and Ingram (2013)  
509 have also reconstructed pluvials around 1750-70 CE and 1810-20 CE, and while less pro-  
510 nounced than the 1600s pluvial, both panels a) and c) show increases in three-day an-  
511 nual maxima during these times. When compared to the model-based modern hydrol-  
512 ogy (dashed black line), both figures suggest that return levels in the most recent 30-  
513 year period are lower than those that have been experienced in prior centuries of the paleo-  
514 period reconstruction. Panels b) and d) show the modern estimates of the three-day an-  
515 nual maxima for the 10-year and 100-year events respectively, in comparison with the  
516 extent of the three-day annual maxima created by the paleo-informed generator. The  
517 ensemble from the generator encompasses the modern estimates of the return levels and  
518 also provides many instances of more extreme flooding events, which provides additional  
519 challenging flood scenarios that can be used to understand the vulnerability of water sys-  
520 tems in each of the Central Valley subbasins explored in this study. As shown in Fig-  
521 ure S10, the rest of the basins display similar three-day annual maxima dynamics, though  
522 the magnitude of the flows differs across all basins and return periods. Lower peak flows  
523 tend to be associated with basins that are smaller in area, elevation, and slope (i.e., New

**Figure 5.** Three-day annual maxima associated with the a) 10-year return period event and c) 100-year return period event for the Don Pedro gauge in the Tuolumne subbasin calculated in 30-year moving windows and across the time period from 1400-2017. The dark green line represents the mean flooding return levels and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile confidence bounds. Panels b) and d) are non-exceedance plots of the three-day annual maxima across the extent of the paleo-reconstruction ensemble. Each gray line represents the sorted three-day annual maxima volumes for each year in a 30-year segment of the paleo-reconstruction. The dashed black line represents the three-day annual maxima associated with the 10-year and 100-year return period events as derived from the SAC-SMA-simulated peak flows when forced with Livneh historical data (1987-2013).

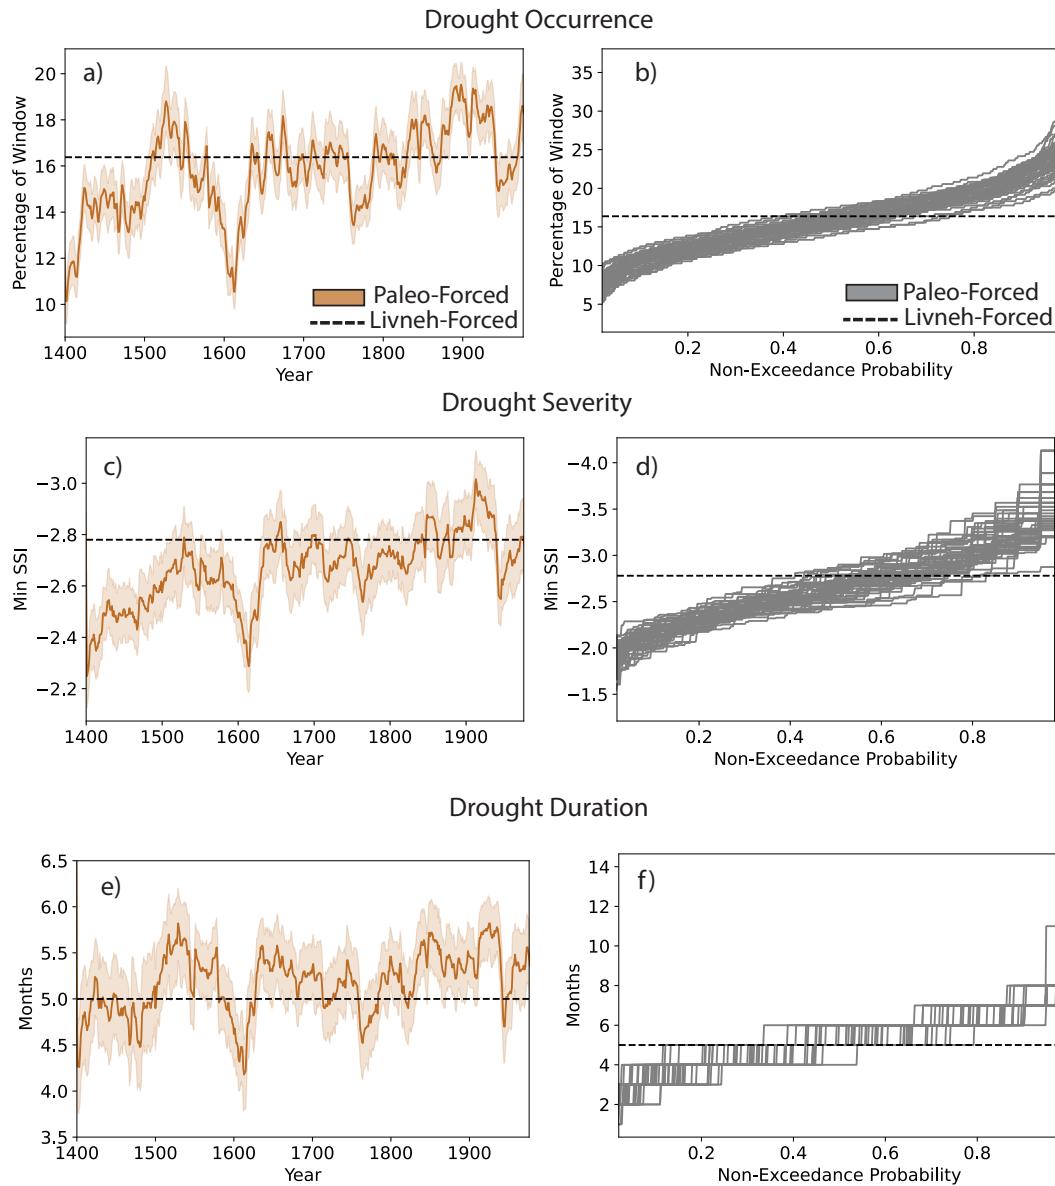

Hogan Lake, Table S1). The ensemble member spread also tends to be larger for the more extreme and uncertain 100-year flood event. Panels a) and c) exhibit clear non-stationary tendencies in the representation of the 10-year and 100-year event across the reconstruction that have large implications for hazard characterization. For example, the flow volumes associated with the 10-year event during the 1600s wet period are within range of the 100-year event flows during the 1500s megadrought period. Thus, what may be considered a 10-year flood event in one wet period transitions to be a 100-year event in a

531 dry period. This extent of variability uncovered in the flood metric demonstrates that  
 532 using only the modern record to define design flood events could severely under-represent  
 533 flood hazard in the Central Valley region and that defining hazard based off of the 10-  
 534 year and 100-year flooding events has drastically changed over time.

535 ***3.2.2 Individual Basin Drought Hazards***

536 Figures 6a,c,e show the three SSI-based hydrologic drought metrics (occurrence,  
 537 duration, and severity) calculated across a 30-year moving window for the period of 1400-  
 538 2017 for the Don Pedro gauge in the Tuolumne River Basin. Figures 6b,d,f are non-exceedance  
 539 plots, where each line corresponds to the sorted drought metric values derived across the  
 540 whole reconstructed 617-year record length for each of the 50 ensemble members. The  
 541 dashed line represents the respective metric values derived from the SAC-SMA model  
 542 flows forced with Livneh historical precipitation and temperature across the length of  
 543 the modern record. Similar to the flooding metrics in Section 3.2.1, the drought met-  
 544 rics exhibit clear decadal-scale variability that is also present in the original WR recon-  
 545 struction from Gupta et al. (2022). For example, Figures 6a,c,e show declines in drought  
 546 occurrence, severity, and duration during the early 1600s pluvial, while these drought  
 547 characteristics become more intense during the 1500s megadrought that lasted from the  
 548 middle of the century to the late 1580s (Stahle et al., 2007). The rest of the San Joaquin  
 549 subbasins display this key behavior as well (Figure S11). The drought metrics reveal a  
 550 slight long-term trend toward higher drought occurrence, longer duration, and more in-  
 551 tense drought severity through the last three centuries of the reconstruction. This trend  
 552 could, in part, be driven by key persistent drought periods that occurred in the mid to  
 553 late 1800s (1856-1865, 1870-1877, and 1890-1896; Herweijer et al. (2006)), the 1900s (the  
 554 Dust Bowl in the 1930s and drought periods in the 1950s and late 1980s; (Stahle et al.,  
 555 2007)) and the most recent 20-year drought periods in the 2000s. The black line demon-  
 556 strates drought occurrence and severity that is on par with the late 1500s megadrought,  
 557 though exhibiting a slightly shorter duration than a large section of the paleo-reconstruction.  
 558 The shorter drought duration is likely due to the sporadic periods of wet weather that  
 559 have characterized the most recent 30-year period, including the early 1980s and late 1990s  
 560 (M. Dettinger & Cayan, 2014) and periods after each drought instance in the 2000s.

561 Panels b), d), and f) compare the modern drought metrics to those calculated from  
 562 the paleo-reconstructed ensembles. The ensembles encompass the modern estimates and

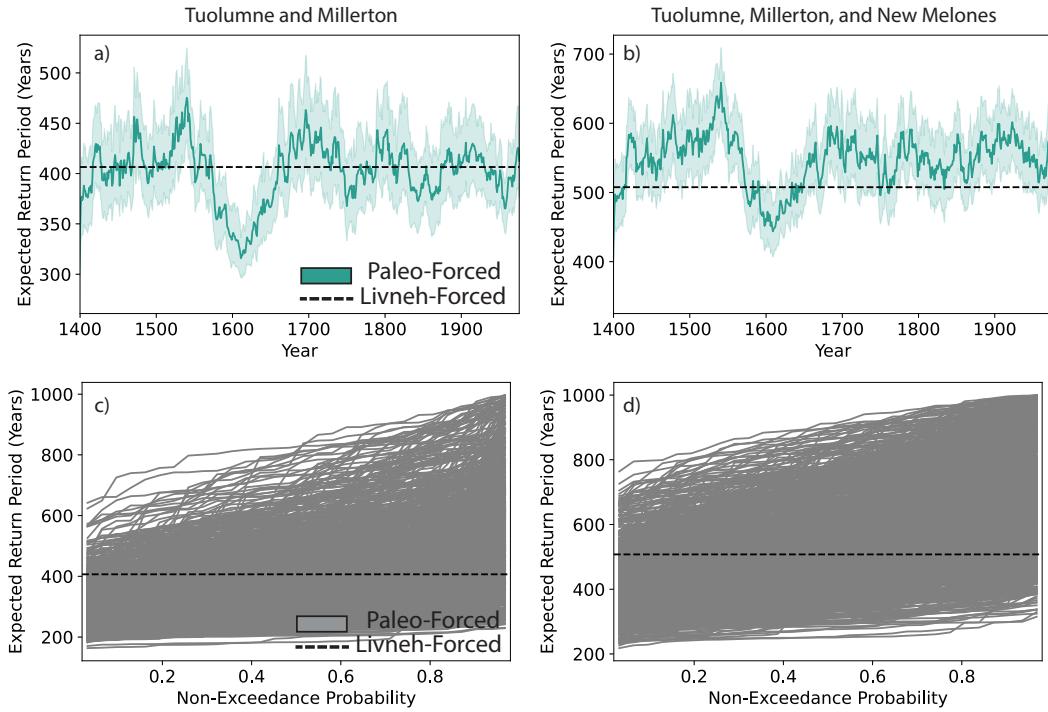

**Figure 6.** SSI-based hydrologic drought metrics of a) occurrence c) severity, and d) duration for the Don Pedro gauge in the Tuolumne Basin calculated in 30-year moving windows and across the time period from 1400-2017. The dark tan line represents the mean drought metric value and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile bounds. Panels b), d), and f) are non-exceedance plots of the three-day annual maxima across the extent of the paleo-reconstruction ensemble. Each gray line represents the sorted three-day annual maxima volumes across the length of the paleo reconstruction. The dashed black line represents the metric values as derived from the SAC-SMA-simulated peak flows associated with the modern record (1987-2013).

563 also provides many traces that are characterized by more frequent, longer, and severe  
 564 drought. The plausibility of the Central Valley subbasins confronting drought conditions  
 565 that extend well beyond those that have been experienced in the modern observed record  
 566 captured in Livneh forcing data is significant even in the absence of climate change. The  
 567 traces in panels b), d), and f) emphasize the need to better characterize the subbasin  
 568 systems vulnerabilities for the challenging drought conditions that are captured within  
 569 the reconstruction.

### 570       ***3.2.3 Joint Flood Hazard Across Basins***

571 Gaussian copulas were fit to the 3-day annual maxima flows for multiple combi-  
 572 nations of basins to characterize joint flood dynamics. The joint probability of flows at  
 573 Don Pedro in the Tuolumne Basin and at Millerton Lake in the Millerton Basin simul-  
 574 taneously exceeding their respective, GEV-based 100-year flood estimates from the most  
 575 recent 30-year period from 1987-2017 was calculated for the length of the reconstruction.  
 576 Figure 7a shows the expected return period associated with those probabilities. Figure  
 577 7b includes New Melones Lake into the joint probability estimation. The return peri-  
 578 ods are calculated using a 30-year moving window across the entire reconstruction. Pan-  
 579 elns c) and d) are non-exceedance plots of the respective return periods across the extent  
 580 of the paleo-reconstruction ensemble. The dashed black line represents the return pe-  
 581 riods for the 10-year and 100-year flood derived from the SAC-SMA model forced with  
 582 Livneh historical precipitation and temperature. As with the flood metrics, in order to  
 583 facilitate the most equivalent comparison between the two datasets, each gray line rep-  
 584 resents the sorted return periods for 30-year segments of the paleo-reconstruction and  
 585 across all 50 ensemble members.

586       As demonstrated in Figure 7, there is a strong increase in the likelihood of simul-  
 587 taneously exceeding the recently observed historical estimate of the 100-year event, par-  
 588 ticularly during the 1600s wet period ( $\sim 20\%$  increase in likelihood). That is, the expected  
 589 frequency of occurrence of simultaneous 100-year flooding events in both the Tuolumne  
 590 and Millerton jumps to once every 320 years, as compared to once every 405 years in the  
 591 most recent 30-year period. There is also a significant decline in the likelihood of joint  
 592 flooding during the late 1500s megadrought. When an additional basin is introduced into  
 593 the copula-based metric, the overall temporal dynamics are similar (Figure 7b), but the  
 594 expected return period increases significantly. That is, the likelihood of simultaneously

**Figure 7.** The expected return periods associated with the joint probability of simultaneously exceeding historical 100-year flood flows at a) Don Pedro (Tuolumne Basin) and Millerton Lake (Millerton Basin), and c) including New Melones (Stanislaus Basin) calculated in 30-year moving windows across the time period from 1400-2017. The dark turquoise line represents the average return period respectively across the ensemble, and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile bounds. Panels b) and d) show the non-exceedance plots for the return periods derived across the whole paleo-reconstruction in 30-year segments. The dashed black line represents the return periods as derived from the SAC-SMA-simulated peak flows associated with the modern record (1987-2013).

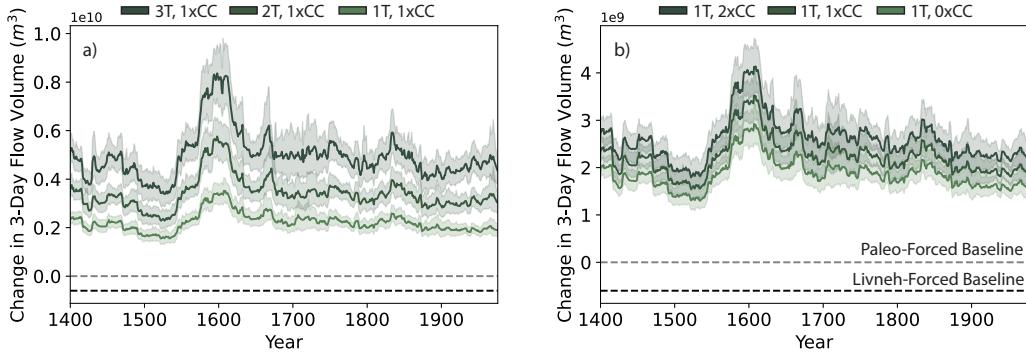

595 exceeding historical flooding thresholds rapidly declines as more basins are considered.  
 596 During the 1600s wet period, the expected frequency of occurrence of simultaneous 100-  
 597 year flooding events in the Tuolumne, Millerton, and New Melones jumps to once ev-  
 598 ery 450 years, as compared to once every 507 years in the most recent 30-year period.  
 599 For both joint flood metrics, the paleo-reconstruction effectively bounds the modern es-  
 600 timation of the return periods, which provides a richer space to characterize joint flood  
 601 hazards across the subbasins (Figures 7c and 7d).

602       Similar non-stationary dynamics as observed in the flooding metrics in Section 3.2.1  
 603       are apparent in these joint flooding metric as well. Simultaneous flooding in all three basins  
 604       is rarer and more consequential for water systems planning and management than simu-  
 605       laneous flooding in the Tuolumne and Millerton alone. Figures 7a-b demonstrate that  
 606       through the paleo-reconstruction, there are periods (like the 1600s wet period) where the  
 607       likelihood of flooding in the three basins becomes just as common as flooding in the Tuolumne  
 608       and Millerton alone (around the late 1500s megadrought). The additional variability that  
 609       the reconstruction provides demonstrates how dramatically the return periods associ-  
 610       ated with these consequential events changes over time, particularly how these flooding  
 611       events can become more frequent. Once again, using the modern record to quantify joint  
 612       hazard across these subbasins could severely underrepresent flood hazards and the mag-  
 613       nitude of design events.

### 614       **3.3 Effects of Thermodynamic Climate Change on Hydrologic Extremes**

#### 615       ***3.3.1 Changes in Individual Basin Flood Hazard***

616       Figure 8 shows the effect of thermodynamic climate changes on the 100-year, 3-  
 617       day flood event in the Tuolumne calculated across 30-year moving windows. The flow  
 618       volumes are represented as deviations from the baseline reconstruction which is shown  
 619       as a gray dashed line at 0. A modern baseline is placed as a dashed black line and is rep-  
 620       resentative of the difference between the modern and the largest 100-year flood event vol-  
 621       ume calculated across the reconstruction. Figure 8a shows scenarios where the precip-  
 622       itation scaling rate is kept at  $7\% \text{ }^{\circ}\text{C}^{-1}$  while temperature is increased by 1, 2, and  $3 \text{ }^{\circ}\text{C}$ ,  
 623       while Figure 8b shows scenarios where the temperature trend is maintained at  $1 \text{ }^{\circ}\text{C}$  and  
 624       the precipitation scaling rate is increased to  $0\% \text{ }^{\circ}\text{C}^{-1}$ ,  $7\% \text{ }^{\circ}\text{C}^{-1}$ , and  $14\% \text{ }^{\circ}\text{C}^{-1}$ . Both  
 625       increasing precipitation scaling rates and temperature trends shift the 100-year flood peak  
 626       flows upwards, though temperature trends have a stronger impact. For reference, the vol-  
 627       ume differential between the extreme scenarios in Figure 8a is equivalent to about 100  
 628       Oroville Dams worth of water. Conversely, the maximum volume differential associated  
 629       with the precipitation scaling in Figure 8b is equivalent to 33 Oroville Dams worth of  
 630       water. The Tuolumne is a snow-dominated basin, and consequently it is not unexpected  
 631       that the results suggest a greater influence on 100-year flows resulting from increasing  
 632       temperature rather than increased precipitation scaling. Increased temperature shifts  
 633       drive increased snowmelt and rain on snow events that promote greater flood volumes.

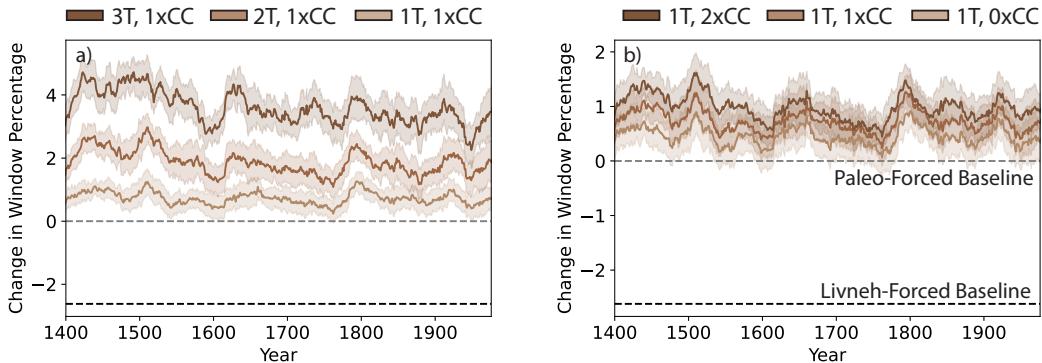

**Figure 8.** The effect of increasing a) temperature and b) precipitation scaling rates on 100-year, 3-day flood flows at Don Pedro (Tuolumne Basin). The dark green lines represent the increase in mean flooding return levels with respect to the baseline scenario (gray line at 0) and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile bounds. A modern baseline (black line) is included as reference and represents the distance from the modern peak flow to the maximum peak flow recorded in the reconstruction.

### 634 3.3.2 Changes in Individual Basin Drought Hazards

635 Figure 9 shows how the same thermodynamic scenarios imposed in Section 3.3.1  
 636 influence drought occurrence in the Tuolumne Basin, measured in terms of a change in  
 637 the percent of the 30-year window that is classified to be in drought conditions with re-  
 638 spect to the baseline scenario (gray dashed line at 0). A modern baseline is placed as  
 639 a dashed black line and is representative of the difference between the modern drought  
 640 occurrence line from Figure 6a and the worst drought occurrence metric calculated across  
 641 the reconstruction. An increase in each of the thermodynamic mechanisms tends to in-  
 642 crease the percentage of the window classified in drought. A comparison across Figures  
 643 9a and 9b show the larger impact of temperature trends on increased drought occurrence  
 644 (reaching up to 5% or an additional 18 months classified in drought) by way of increased  
 645 evapotranspiration. Precipitation scaling stretches the daily precipitation distribution  
 646 which can lead to tail influences that impact the total number of drought months, but  
 647 has a lower relative influence (reaching up to 1.8% or an additional 6 months classified  
 648 in drought). For example, there are some instances, particularly in the 1T, 1xCC sce-  
 649 nario in Figure 9a that result in values that approach the baseline. This is likely due to  
 650 the precipitation scaling mechanism causing some months to have an increased SSI above  
 651 the drought threshold that offsets the temperature increase. However, as the temper-

ature shift further increases, this effect is dominated. Figure S12 shows the same results for drought severity and duration. Overall, there is a greater influence from increasing temperature trends to increasing drought severity and duration. It's worthwhile to note that the impact from both temperature trends and precipitation scaling is relatively small (Figure S12c,d) with respect to increasing consecutive months classified in severe drought and these results are further reflected in Figure 12.

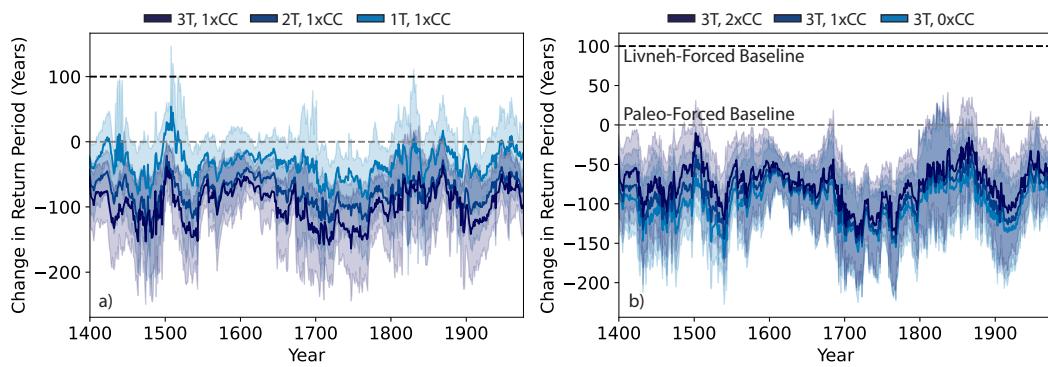

**Figure 9.** The effect of increasing a) temperature and b) precipitation scaling rates on drought occurrence at Don Pedro (Tuolumne Basin). The dark brown lines represent the increase in the percentage of the 30-year window classified in drought conditions with respect to the baseline scenario (grey line at 0) and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile bounds. A modern baseline is included (black line) as a reference and represents the distance from the modern drought occurrence metric to the worst drought occurrence recorded in the reconstruction.

### 658 3.3.3 Joint Flood Hazard Across Basins

659 Figure 10 shows how similar thermodynamic scenarios influence joint flood hazard  
 660 at Don Pedro (Tuolumne Basin) and Millerton Lake (Millerton Basin), measured in  
 661 terms of change to return period associated with the 100-year event with respect to the  
 662 baseline scenario (gray dashed line at 0). As with the prior sections, a modern dashed  
 663 black baseline is included to represent the difference between the modern return period  
 664 estimate and the lowest return period calculated across the reconstruction. Much like  
 665 Figure 8, Figure 10 demonstrates a larger influence from increasing temperature trends  
 666 on making compound flooding events more likely (Figure 10a). Given that the Tuolumne  
 667 and Millerton are both snow-dominated basins, temperature trends create similar snowmelt

668 effects that lead to simultaneous flooding events. Precipitation scaling has a relatively  
 669 reduced, but non-trivial effect (Figure 10b). The greatest influence from precipitation  
 670 scaling is observed under higher imposed temperature trends (we use a constant 3°C tem-  
 671 perature trend in this example). While an increase in precipitation scaling increases the  
 672 likelihood of flooding in any given basin (Figure 8b), Figure 10b demonstrates that it  
 673 decreases the likelihood of joint flooding, and makes the events rarer by increasing the  
 674 return period. Since the imposed precipitation scaling non-linearly adjusts peak flows,  
 675 it ultimately leads to a decrease in correlation in flows across the two basins and there-  
 676 fore a decrease in joint flooding tendencies.

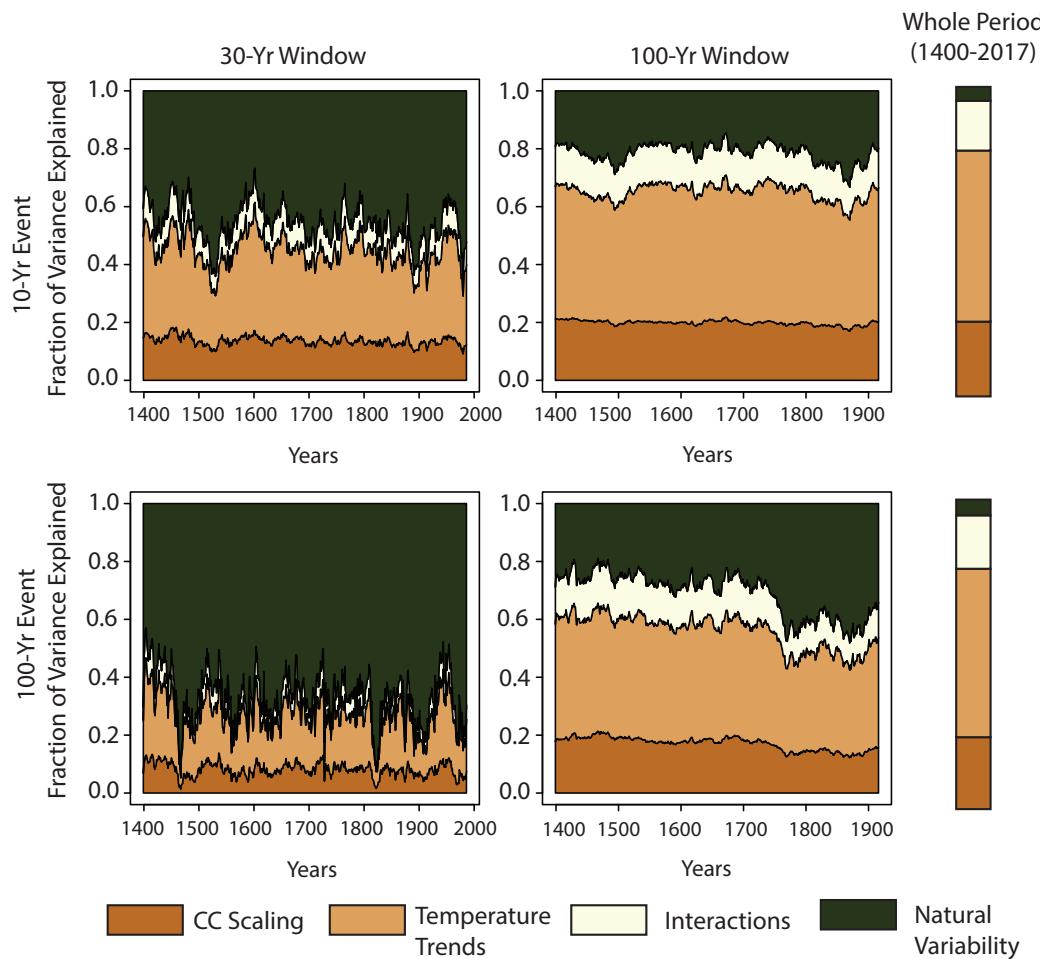

**Figure 10.** The effect of increasing a) temperature and b) precipitation scaling rates the change in return period associated with simultaneously exceeding historical 100-year-day flood flows at Don Pedro (Tuolumne Basin) and Millerton Lake (Millerton Basin). The dark blue lines represent the change in return period with respect to the baseline scenario (gray line at 0) and the shading represents the 5<sup>th</sup> and 95<sup>th</sup> percentile bounds. A modern baseline (black line at 0) is included as reference and represents the distance from the modern return period to the shortest return period recorded in the reconstruction.

### 677 3.4 Variance Partitioning of Hydrologic Extremes

678 The results above show how different metrics of hydrologic extremes vary signif-  
 679 icantly over time due to natural climate variability as well as different mechanisms of cli-  
 680 mate change. Below we use variance partitioning to assess the relative importance of these  
 681 competing factors.

682           **3.4.1 Relative Variance Contributions for Individual Basin Flood Haz-**  
 683           **ard**

684           We conduct an ANOVA to partition the variance of the 10-year and 100-year 3-  
 685           day floods for each gauged location. Figure 11 shows the results for Don Pedro, while  
 686           results for the other sites are shown in Figure S13-S16. The columns show the results  
 687           of the decomposition when flood metrics are derived with a 30-year, 100-year, and 617-  
 688           year (whole record) time horizon, respectively.

**Figure 11.** A decomposition of the key drivers of variance in the flood metrics for the Don Pedro gauge in the Tuolumne River Basin for a,d) 30-year time horizon b,e) 100-year time horizon and c,f) a 617-year time horizon.

689           Two main insights emerge from Figure 11. First, natural variability is the primary  
 690           driver of the variance when the flood metrics are calculated using a 30-year time hori-

zon (Figures 11a,d). This is especially true for the 100-year flood, where approximately 70% of the variance in this metric is associated with natural variability. Figure 11d has direct relevance to the design standards actively used to inform California's flood planning and management. However, the influence of natural variability on the spread in flood metrics across the ensemble substantially decreases when the metric is calculated across a 100-year time horizon (Figures 11b,e), and becomes almost negligible when calculated over the entire 617-year period (Figures 11c,f). This suggests that the time horizon over which the flood metrics are calculated highly influences the perception of key drivers. A longer time horizon more clearly captures the effects of longer-term climate change on the variation in the flood metrics, while during shorter windows the variation in flood metrics across the ensemble is more likely to capture noise associated with natural variability. The reasons for this are twofold. First, when the time horizon is large, each ensemble member for a particular climate change scenario contains many annual maxima that are all drawn from the same underlying climate state, helping to converge design event estimates across ensemble members towards similar values. Second, when the time horizon is large, there are more opportunities for climate change signals to influence the distribution of annual maxima flows for all ensemble members under a given climate change scenario, which will help separate the distribution of annual maxima across the different scenarios. Together, these two factors will lead to more variance in the overall ensemble being explained by the climate change scenarios compared to natural variability.

Of the thermodynamic changes, temperature trends are the primary driver of variation in peak flows, followed by precipitation scaling. This result, also seen in Figure 8, suggests that temperature increases that lead to increased snowmelt and rain on snow events influences peak flows in the region more than increases in extreme precipitation due to increased moisture in the atmosphere. The interactions between the two drivers generally accounts for a smaller percentage of the variance, but as the time horizon increases, interactive effects are close to the same magnitude as precipitation scaling (16% vs. 24% for the whole period). This result highlights how the effects of precipitation scaling are dependent on the temperature increase, because precipitation scaling is parameterized as a percentage change in extreme precipitation per °C warming.

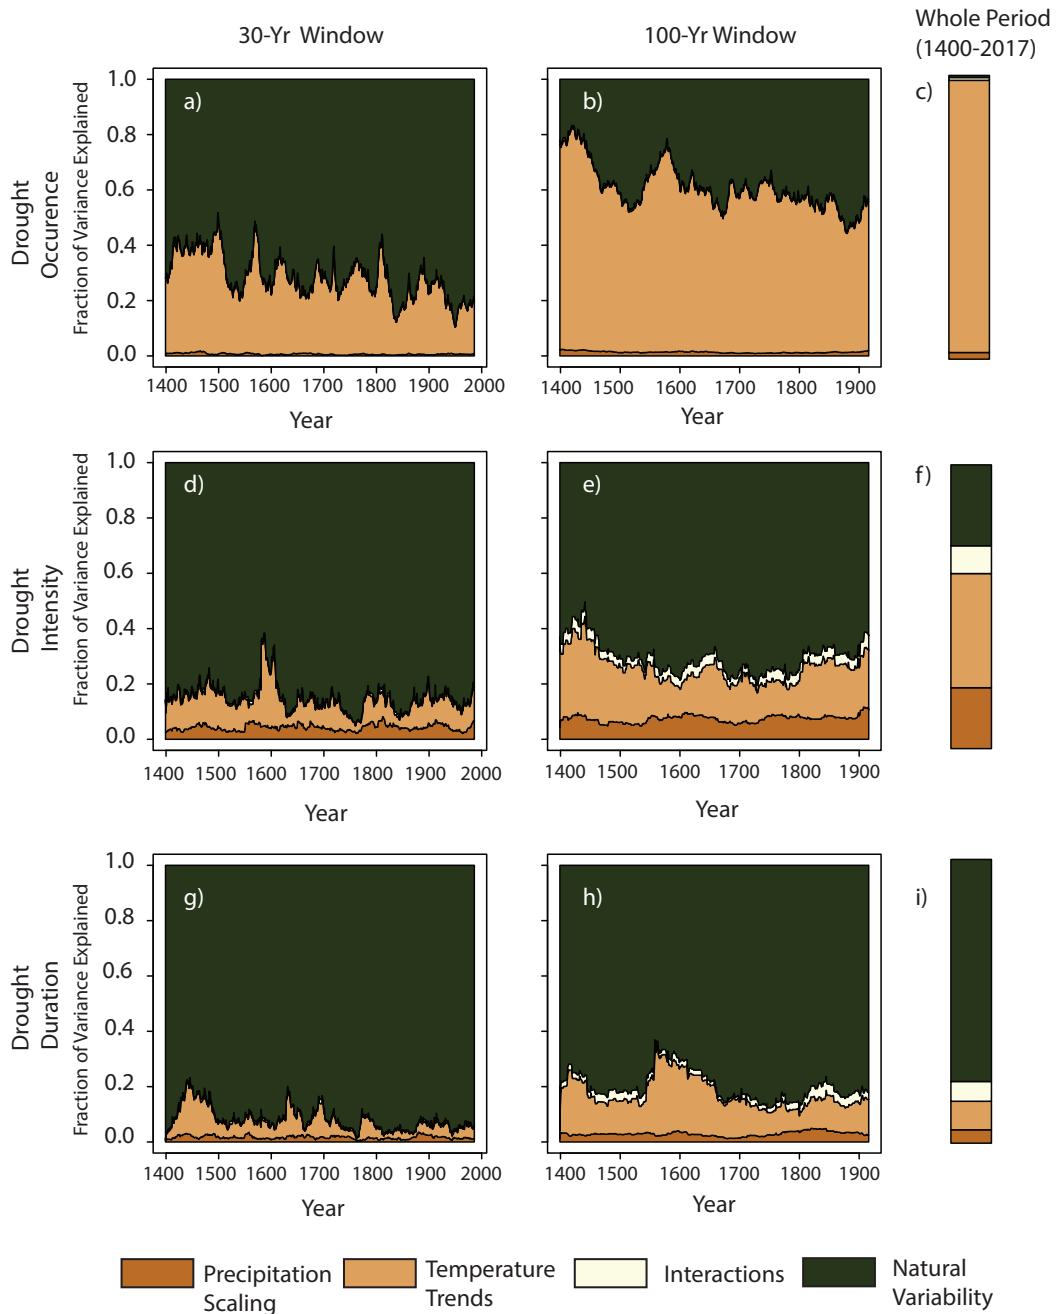

Figure S13-S16 show the same results for the remaining four basins. Overall, all basins exhibit similar behavior, where the influence of natural variability decreases with

time horizon. Temperature change has a larger impact than precipitation scaling in all basins except for New Hogan Lake (Figure S15). New Hogan Lake is relatively small, has a low elevation, and less snow dominated compared to the other basins (Table S1), and thus sees a greater influence from precipitation scaling on flood variability.

Overall, the results in Figure 11 portray conflicting storylines and complexity for flood planning and management depending on the way the flood metrics are defined. Under current CA planning conditions (represented in Figure 11d), the greater influence of natural variability on individual flood hazard would suggest prioritizing short-term adaptive tools like seasonal forecasts. However, under alternative planning scenarios that may utilize longer time horizons, infrastructure investments look to be more useful to manage hazards from thermodynamic climate changes. Most importantly, water planners will need to engage with both drivers; prioritizing longer horizons of focus could neglect the effects of internal variability in the near term, which as Figure 5 portrays, can lead to magnitudes of peak flows that far surpass those in the modern record. Ultimately, there needs to be consideration of both the exceptional magnitude of internal variability in more immediate decision relevant 30-year timescales while still being cognizant of the longer-term climate changes. Thus, it's important for water resources agencies that utilize dynamic and adaptive planning methods to effectively balance the value, resilience, and potential regrets of near term investments (e.g. Haasnoot et al. (2013); Schlumberger et al. (2022)).

#### **3.4.2 Relative Variance Contributions for Individual Basin Drought Hazards**

Figure 12 shows the ANOVA decomposition for drought occurrence, intensity, and duration for 30-year and 100-year moving windows, as well as the entire 617-year period. The variance partitioning for drought occurrence follows a similar pattern to the flood metrics above (Figures 12a-c). For short time horizons of 30 years, about 20-40% of drought occurrence variability across the ensemble is associated with natural variability. However, as the time horizon grows, more variance is partitioned to the climate changes, and for extremely long horizons, almost all of the variance in drought occurrence across the ensemble is associated with climate change. Specifically, temperature change becomes the near-sole driver of drought occurrence variability, likely because of the strong increases in evapotranspiration with warming that drive drought occurrence.

**Figure 12.** A decomposition of the key drivers of variance in the drought metrics for the Don Pedro gauge in the Tuolumne River Basin for a,d,g) 30-year window b,e,h) 100-year window and c,f,i) a 600-year window.

For drought intensity, we see a similar pattern in variance partitioning between natural variability and climate change factors, but the magnitude and degree of change in the variance partitioning more heavily favors natural variability (Figures 12d-f). For 30-

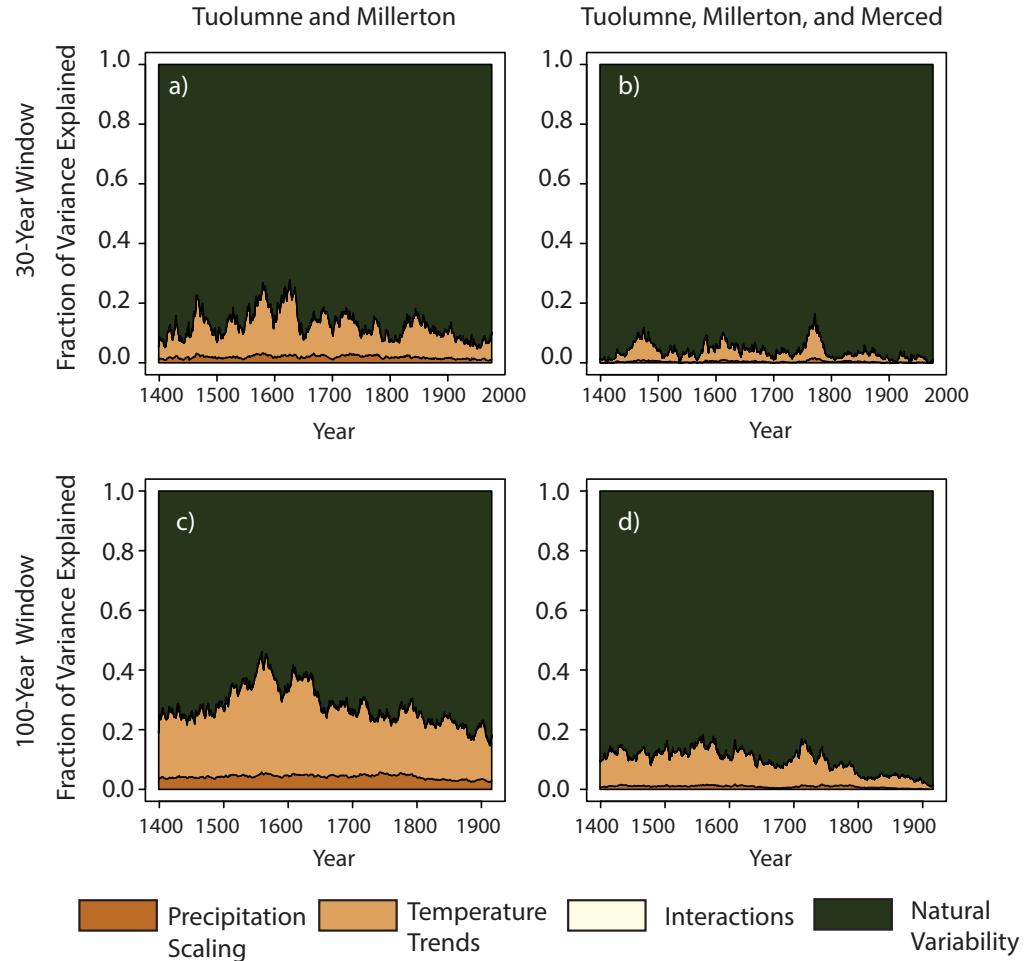

759 year windows, natural variability accounts for upwards of 80% of the total variance in  
760 drought intensity, and this falls to the (still substantive) value of 28% when the window  
761 reaches 617 years. Of the climate changes, temperature trends once again are the main  
762 driver, but precipitation scaling and interactive effects also play an important role in drought  
763 intensity variability across the ensemble. Given that the mechanism of precipitation scal-  
764 ing stretches the daily precipitation distribution such that large precipitation values be-  
765 come larger and small precipitation values become smaller, we see a more significant in-  
766 fluence from this mechanism on drought intensity than in the other metrics.

767 Unlike the other two drought metrics, drought duration is primarily driven by nat-  
768 ural variability, even when the metric is derived across the longest window. Drought du-  
769 ration generally is linked to the length of time in which there is no precipitation. None  
770 of the imposed climate changes directly affects this behavior in the same manner that  
771 precipitation scaling directly influences drought intensity or temperature trends affect  
772 drought occurrence. Temperature increases can somewhat extend drought duration by  
773 increasing evapotranspiration at the beginning and end of a drought period (Figure 12h),  
774 but ultimately the duration of a drought is dictated by the occurrence of large storms  
775 that end the drought, which is primarily driven by natural variability in our climate sce-  
776 narios. The decomposition results for the remaining four gauged locations are presented  
777 in Figure S17-S20. These gauged locations show similar behavior as the Don Pedro gauge.  
778 Temperature trends play a large role in influencing drought occurrence, and this influ-  
779 ence is particularly large in Merced and New Melones Lake (S17a, S20a). Precipitation  
780 scaling plays a small role in drought occurrence, and drought duration is primarily driven  
781 by natural variability.

782 The drivers of drought are more complex than the flood hazard metrics due to the  
783 heterogeneity of behavior across the drought metrics. A comparison between Figures 12a,d,  
784 and g demonstrate vast differences in drivers (and therefore approaches for managing  
785 drought) depending on exactly what characteristic of drought is prioritized in planning.  
786 The choice of time horizon further complicates the understanding of the appropriate plan-  
787 ning process, especially in the case of drought occurrence (Figures 12a,b). However, drought  
788 intensity and drought duration show more stable influence primarily by natural variabil-  
789 ity and would consequently need a mix of carefully coordinated shorter-term adaptive  
790 actions (e.g., water transfers, conservation, and shifts in allocative priorities to higher  
791 value uses) that provide flexibility to improve the robustness of longer-term infrastruc-

ture investments to extreme variability in Central Valley drought regimes (e.g., improved conveyance, groundwater banking, managed aquifer recharge, and others; Herman et al. (2020); Hamilton et al. (2022)).

### 3.4.3 Relative Variance Contributions for Joint Flood Hazard

**Figure 13.** A decomposition of the key drivers of variance in joint flood metrics for a),c) Tuolumne and Millerton and b,d) Tuolumne, Millerton, and Merced.

Figure 13 shows the variance partitioning for the copula-based joint flood hazard metric in two cases: (1) bivariate flood risk in the Tuolumne and Millerton (Figure 13a,c); and (2) trivariate flood hazard in the Tuolumne, Millerton, and Merced (Figure 13b,d), both for the 100-year, 3-day flood. In both cases, the primary driver of joint flood hazard is natural variability. Unlike flood hazard for individual basins (see Figure 11), the

801 contributions of natural variability to the total variance joint flood hazard does not de-  
802 cline substantially with time horizon. Additionally, as more locations are considered when  
803 quantifying joint flood hazard, natural variability becomes an even more prominent driver  
804 of spatially compounding major flood hazards. These results suggest that the dominat-  
805 ing factor that dictates whether basins experience simultaneous large flooding is largely  
806 randomness in storm tracks and the associated spatial distribution of extreme precip-  
807 itation and temperature-driven snowmelt. The thermodynamic climate changes that in-  
808 fluence snowmelt or scale up storms do play a role, particularly if the basins are in close  
809 proximity (such as the Tuolumne and Millerton in Figures 13a,c). However, as more basins  
810 are included, natural variability in the weather during large storms dominates. Figure  
811 13 reveals the inherent challenges of managing for spatially compounding flood hazards  
812 in this region. If persistent climate changes are a more dominant factor in driving joint  
813 flooding across all basins, then shared investments in canal expansion or rehabilitation  
814 across the regions could be used to offset some of this risk. However, since natural vari-  
815 ability is the key driver of large flooding, alternative methods of creating unified plan-  
816 ning and management strategies again need to be considered, using a mix of carefully  
817 coordinated shorter-term adaptive actions that provide flexibility to improve the robust-  
818 ness of longer-term infrastructure investments to the extreme hydro-climatic variabil-  
819 ity of the Central Valley (Herman et al., 2020; Hamilton et al., 2022).

## 820 4 Conclusion

821 This study contributes a novel framework to better understand the relative role of  
822 natural climate variability and climate change in determining the uncertainty in future  
823 hydrologic extremes of great importance to water systems planning and management.  
824 This framework is complementary to similar approaches based on GCM ensembles, but  
825 instead utilizes a large stochastic ensemble of paleo-based weather and hydrologic sim-  
826 ulations to capture the plausible range of natural variability in drought and flood dy-  
827 namics. The impacts of pre-selected mechanisms of climate change, including shifts in  
828 temperature and precipitation scaling, are then incorporated into the ensemble. The vari-  
829 ance in hydrologic extremes is then partitioned across those climate changes and nat-  
830 ural variability in the ensemble.

831 We first demonstrate the utility of the generator forced with paleodata in captur-  
832 ing and expanding on the dynamics of the modern record, which makes it a particularly

useful for facilitating exploratory modeling and further quantification of the robustness of water resources systems to challenging scenarios that have been seen in the region's past hydroclimate. We also highlight the large non-stationarity that exists in the flood and drought metrics through the length of the reconstruction, particularly taking note of consequential 100-year flooding periods that can become as likely as 10-year events in parts of the record (i.e., 10 times more likely). These results have large implications for commonly employed stationary analyses, such as deriving design event estimates from the modern record, to quantify flood risk in this region. Our results suggest that these techniques severely underrepresent hydro-climatic hazards and the magnitude of design events that infrastructure should be built for.

The results of the variance decomposition component of the study highlight the following main conclusions:

- Uncertainty in future flooding within individual basins is largely driven by thermodynamic climate change, especially if evaluated over long time horizons. Flooding within snow-dominated basins is primarily driven by changes in temperature, while lower-elevation basins see a greater influence from precipitation scaling.
- The relative importance of climate change and natural variability on the uncertainty in future drought depends on the drought metric of interest. Changes in temperature drive drought occurrence, while precipitation scaling plays a role in drought intensity. Drought duration is primarily driven by natural variability.
- The uncertainty in simultaneous flood hazard across multiple basins is largely driven by natural variability, and this influence increases as additional basins are considered.
- The perception of the most important driver is highly influenced by the time horizon over which a metric is calculated. Shorter time horizons are less likely to capture how climate change uncertainty influences the uncertainty in hydrologic extremes.

The variance decomposition reveals a complicated path to robust planning and managing for both flood and drought in the region. The results suggest that natural variability and climate change influence both extremes to varying degrees. Furthermore, different characteristics of a single extreme (i.e. drought occurrence and duration) can be influenced by different drivers.

865        Additionally, if different time horizons are prioritized for planning for extremes, the  
866        understanding of the most important drivers of flood and drought hazards also changes.  
867        This last facet especially presents a problem for adaptive planning and management. This  
868        type of planning triggers management decisions based on the evolution of an observed  
869        variable (including hydroclimatic variables like precipitation or streamflow) over a spe-  
870        cific horizon. As demonstrated in our study, tracking peak flows over a 30-year or 100-  
871        year horizon are both appropriate for longer-term flood management, but prioritizing  
872        the latter could neglect the effects of internal variability in the near term while increas-  
873        ing the potential for maladaptive longer-lived capital investments in infrastructure. Thus,  
874        it's important for water resources agencies that utilize these dynamic planning methods  
875        to effectively balance the value and potential regret of near term investments (Herman  
876        et al., 2020; Schlumberger et al., 2022).

877        One of the most important results of our study is that natural variability plays a  
878        very large role in dictating the future uncertainty in key metrics of flood and drought  
879        that form the basis of water resources planning; at times much larger than that of promi-  
880        nent climate change signals. This suggests that better quantification of the true range  
881        of natural variability in these extremes should be a major priority for the climate and  
882        hydrologic research community, and equally important, these efforts should directly in-  
883        form future planning efforts for water resources systems. However, historically, this has  
884        often not been the case, with concerns about climate change often overshadowing the  
885        potential impacts of natural variability (see discussions in Koutsoyiannis (2020, 2021)).

886        Our results show, in particular, the importance of natural variability on spatially  
887        compounding flood hazard, which arguably poses a more difficult and complex manage-  
888        ment problem than addressing hazards in any one basin due to the need for infrastruc-  
889        ture coordination across space and time. This highlights the potential value that longer,  
890        paleo-based data could bring to the estimation of joint flood hazards. The field of pa-  
891        leoflood hydrology has historically focused on the identification and dating of flood ev-  
892        idence in fluvial sedimentary archives, but incorporating speleothems and botanical archives  
893        can substantially increase the comprehensiveness and quality of paleoflood data (Wilhelm  
894        et al., 2018). Alluvial archives are also being used in more densely-populated and flood-  
895        prone regions (Toonen et al., 2020), and recent studies have shown that incorporation  
896        of these data can significantly reduce the uncertainty of extreme flood estimates (Engeland  
897        et al., 2020; Reinders & Muñoz, 2021). Methodological advances that can use these new

898 and diverse data sources to constrain joint flood hazard estimates across sites would be  
899 particularly helpful, as would guidance on how to appropriately and consistently incor-  
900 porate paleodata into risk management practices that also consider the effects of climate  
901 change. The work of England Jr et al. (2019) that helped incorporate paleodata into U.S.  
902 flood frequency guidance (Bulletin 17C) provides inspiration for such an approach.

903 The results also highlight the significant impact of natural variability on drought  
904 uncertainty, especially drought duration and intensity, and the implications stated above  
905 for joint flood hazards also extend to drought hazards. There are state-of-the-art tech-  
906 niques currently being applied within the dendrochronology community that can help  
907 improve our understanding of the natural range of drought variability. Beyond using tree  
908 ring widths, some studies are isolating earlywood and latewood signals for better drought  
909 reconstruction (Soulé et al., 2021; Song et al., 2022) or using blue intensity (the inten-  
910 sity of reflectance of the blue channel light from a wood core) to identify more stable climate-  
911 growth relationships that inform more robust reconstructions (Akhmetzyanov et al., 2023).  
912 Furthermore, better forecasts could provide water managers with more effective ways to  
913 navigate drought caused by natural variability. Skillful near-term drought predictions  
914 have been achieved by using decadal hindcasts from CMIP6 (Zhu et al., 2020) and Ma-  
915 chine learning based approaches, particularly those that can model catchment memory  
916 are being used to create skillful seasonal drought predictions (Amanambu et al., 2022;  
917 Sutanto & Van Lanen, 2022)

918 One key limitation of this work is that we only consider a subset of plausible cli-  
919 mate change scenarios that are not comprehensive, but rather reflect two mechanisms  
920 of change that are likely to occur and to be consequential to the San Joaquin Valley in  
921 California. This limitation includes the omission of the possibility that properties of long-  
922 term climate variability will itself change in the future under climate change. Another  
923 limitation is that we represent natural variability with one statistical model based on his-  
924 torical and paleo data. As others have shown (Koutsoyiannis, 2021), the quantification  
925 of natural variability often greatly depends on the statistical model used.

926 While outside the scope of this study, the framework presented and conclusions drawn  
927 here would benefit from a direct comparison against a similar approach using a climate  
928 ensemble drawn from a GCM, especially a single model initial-condition large ensemble  
929 (SMILE; see Lehner et al. (2020)). In a SMILEs-based framework, projections of pre-

930 precipitation and temperature derived from a single GCM under multiple initial conditions  
931 and multiple emission scenarios could be downscaled and propagated through hydrologic  
932 models to create a future streamflow ensemble, which could be used for partitioning vari-  
933 ance in hydrologic extremes across emission scenarios and natural variability. By com-  
934 paring results between the framework of this study and a SMILEs-based framework, one  
935 could better understand whether and how the relative roles of natural variability and  
936 climate change are consistent or depend on methodological choice.

937 Regardless of method used, the results of this work strongly suggest that large en-  
938sembles of natural variability are likely needed to adequately assess future risks to wa-  
939 ter resources systems that are particularly sensitive to extreme events. In future work,  
940 we intend to pair the hydrologic ensembles developed here with a regional, multi-sector  
941 model of California's Central Valley (Zeff et al., 2021) to more fully assess the risk that  
942 future hydroclimate extremes pose to stakeholders across the system, including ground-  
943 water banks and irrigation districts. The ultimate goal of such work is to facilitate a greater  
944 understanding of how future extremes lead to heterogeneous shortage and flooding im-  
945 pacts across stakeholders, and to help identify robust adaptation strategies to address  
946 these future risks.

1249 **Appendix A: Glossary of Terms**

- 1250 • **Baseline weather scenario:** The 600-year daily precipitation and temperature  
1251 scenario that is created by forcing the weather generator with paleo-reconstructed  
1252 weather regimes. This scenario is comprised of 50 stochastic ensemble members.
- 1253 • **Baseline streamflow scenario:** The 600-year daily streamflow scenario acquired  
1254 by driving the hydrologic model with paleo-reconstructed weather (often referred  
1255 to as 0T, 0CC). This scenario is comprised of 50 stochastic ensemble members.
- 1256 • **Climate scenario:** A 600-year daily streamflow scenario created by forcing the  
1257 hydrologic model with a baseline weather scenario that is layered with a set of ther-  
1258 modynamic climate changes.
- 1259 • **Ensemble member:** Also referred to as a stochastic realization; each climate sce-  
1260 nario is comprised of 50 stochastic ensemble members
- 1261 • **Record length:** The total length of the dataset
  - 1262 – **Paleo-informed weather and streamflow datasets:** 617 years (1400-2017  
1263 CE) at a daily time scale
  - 1264 – **Observed Livneh climate (temperature and precipitation) dataset:** 63  
1265 years (1950-2013 CE) at a daily time scale
  - 1266 – **Observed CDEC streamflow dataset:** 33 years (1986-2019) at a daily time  
1267 scale
- 1268 • **Time horizon:** also referred to as moving window; the length (in years) of the  
1269 sliding window that passes over the total record length.

1270

## Appendix B: Metrics and Time Horizons

Metric	Description	Calculated	Justification	Citation
Flood Metric	10-Year Return Period Flow	GEV fit to 3-day maximum flow	Captures risk to smaller flood-plains (or nuisance flooding in larger areas) and drives smaller investments.	Progress on Incorporating Climate Change into Planning and Management of California's Water Resources (July 2006)
Flood Metric	100-Year Return Period Flow	GEV fit to 3-day maximum flow	Drives larger riverine infrastructure development and flood risk management. Requires FEMA-mandated insurance.	Central Valley Flood Protection Plan Update 2022 (November 2022)
Drought Metrics	Occurrence, Severity, and Duration	Standardized streamflow-based indices	No state-wide definition. Historical droughts have been identified based on a combination of metrics such as reservoir depth and deficit magnitude and duration.	California's Most Significant Droughts: Comparing historical and recent conditions (February 2015)

Spatially Compounding Flood Metric	Likelihood of simultaneously exceeding historical 10-year and 100-year flow events in $n$ basins	$n$ -dimensional Gaussian copula	Flooding across the San Joaquin system could result in infrastructure failure such as levee breaks and disrupt deliveries of fresh water to 3 million acres of farmland.	Managing Floods in California (March 2017); Zscheischler et al. (2020)
Time Horizon	30-Year	N/A	CA prioritizes investment in flood management over a 30-year planning horizon	Central Valley Flood Protection Plan Update 2022 (November 2022)
Time Horizon	100-Year	N/A	Not actively used in planning and management, but can represent longer-term investments.	N/A
