13

14 Three key points:

15   1. *In situ* O_2/Ar data aggregated over three cruises reveal a hotspot of net community

16   production to the north of the Kuroshio Extension Front.

17   2. The correlation between net community production, chlorophyll and sea level

18   anomaly (a proxy for mesoscale eddies) varies regionally and seasonally.

19   3. In aggregate, a region of high net community production is associated with the

20   Kuroshio nutrient stream, whereas chlorophyll varies with latitude.

21

Abstract

The Kuroshio current separates from the Japanese coast to become the Kuroshio
Extension (KE) characterized by a strong latitudinal density front, high levels of
mesoscale (eddy) energy, and high chlorophyll (CHL). Recent work has also shown that
the KE carries subsurface nutrients into the region horizontally. While satellite
measurements of CHL show evidence of the impact of eddies on the standing stock of
phytoplankton, there have been very limited *in situ* estimates of productivity over
synoptic scales in this region. Here, we present highly spatially resolved estimates of net
community production (NCP) for the KE region derived from underway O_2/Ar
measurements made in spring, summer, and early autumn. We find large seasonal
differences in the relationships between NCP, CHL, and sea level anomaly (SLA, a proxy
for local thermocline depth deviations driven by mesoscale eddies). The KE front is a
pronounced hotspot of NCP in spring when NCP is almost completely decorrelated with
CHL. Conversely, we find that NCP and CHL are strongly correlated in summer away
from the front. We explore the mechanistic underpinnings of the relationship between
NCP and CHL and suggest that the KE nutrient stream as well as vertical motions
associated with mesoscale eddies might be a key factor in supporting an NCP hotspot that
is seasonally decoupled from CHL at the KE front. Our observations also highlight
seasonal and regional (de)coupling between NCP and CHL which may impact the
accuracy of CHL-based estimates of productivity.

Plain Language Summary

Biological processes in the surface ocean play an important role in the ocean carbon
cycle. Phytoplankton transform carbon dioxide into organic material, a portion of which
then sinks into the deep where it can be stored long-term. This mechanism of carbon
transfer from the surface to the deep ocean is known as the biological carbon pump. The
processes that mediate this biological carbon pump can occur over short time and space
scales. This is especially true in dynamic ocean systems such as western boundary
currents where there are local maxima in weekly to interannual variability within the
boundary current itself. Here we use novel continuous measurements made from ships of

52   opportunity to explore the variability in productivity and chlorophyll and how they are

53   connected to physical ocean dynamics.

1. Introduction

The biological pump, the export of organic carbon from the surface to the deep ocean, plays a key role in the global carbon cycle. Inorganic carbon is converted to organic carbon by phytoplankton in the surface ocean through photosynthesis. A portion of this organic carbon is then exported from the surface and remineralized as it sinks through the water column, and is ultimately stored in the deep ocean with residence times of many months to centuries [*DeVries et al.*, 2012; *Giering and Humphreys*, 2018]. The processes that control the production, consumption, packaging, and export of organic carbon occur over relatively short time scales, from days to months, associated with biological processes, ecosystem dynamics and the evolution of the surface mixed-layer and mesoscale motions. More specifically, the time scales that control the production and export of carbon from the surface ocean span the division rate of phytoplankton cells O(1 day^{-1}), bloom events that last for weeks, and the seasonality of organic carbon production over the annual cycle in the mid and high latitudes. The spatial distribution of biogeochemical tracers in the surface ocean is also known to be very patchy, varying widely over scales as fine as O(<1km) [*Mackas et al.*, 1985; *van Gennip et al.*, 2016] up to basin scales O(1000km). This temporal and spatial variability presents a challenge to observing and understanding the drivers that control the production and export of organic carbon, particularly in highly dynamic ocean regions such as western boundary currents.

1.1 Measuring net community production in situ

Synoptic measurements of physical, chemical and biological parameters made at appropriate scales are necessary to understand the balance of processes that control rates of productivity and export. These types of measurements are also necessary to determine whether these processes are fully resolved, or at least well parameterized, in large-scale climate models used to make predictions about changes in ocean biogeochemical processes, and their impact on the global carbon cycle. However, measuring productivity *in situ* can be challenging as traditional bottle methods for estimating productivity rates are labor-intensive and do not allow for a large number of estimates to be made either at high resolution or synoptically over large areas. Remotely sensed productivity estimates can be made over large areas, but do not resolve fine scale variability and are subject to

substantial uncertainty [*Palevsky et al.*, 2016b]. As a result, although it is well-known

that phytoplankton standing stocks (e.g. measured by chlorophyll fluorescence, cell

counts and particulate organic carbon) are extremely patchy in time and space [*Mackas et*

al., 1985], little is known about the scales of variability of rates of productivity and

export.

Non-incubation-based dissolved gas tracers have been used to derive synoptic, high-

resolution estimates of biological carbon export. Net community production (NCP, mmol

C m^{-2} day^{-1}) is the net sum of the organic carbon produced by gross primary production

(GPP, mmol C m^{-2} day^{-1}) and the organic carbon remineralised by respiration by both

heterotrophs (R_{HET}) and autotrophs (R_{PHY}) in the surface mixed layer:

$$NCP = \underbrace{GPP - R_{PHY}}_{NPP} - R_{HET} \qquad (1)$$

where NCP values are positive in net autotrophic systems, and negative in net

heterotrophic systems. Net primary production (NPP) is the net sum of GPP and

respiration by phytoplankton. In steady state conditions with no transient change in the

surface biomass concentration, NCP represents the rate of organic carbon export from the

mixed layer. NCP can be estimated based on the biological supersaturation of dissolved

oxygen in the mixed layer, determined from the O_2/Ar dissolved gas ratio [*Craig and*

Hayward, 1987; *Emerson et al.*, 1991]. The development of continuous underway

methods to measure O_2/Ar [*Cassar et al.*, 2009; *Tortell*, 2005] has enabled new fine

spatial-scale estimates of NCP, which have been widely applied in both coastal and open

ocean regions [*Castro-Morales et al.*, 2013; *Estapa et al.*, 2015; *Eveleth et al.*, 2017; *R C*

Hamme et al., 2012; *Izett et al.*, 2018; *Kaiser et al.*, 2005; *Lockwood et al.*, 2012;

Manning et al., 2017; *Palevsky et al.*, 2013; *Rosengard et al.*, 2020; *Stanley et al.*, 2010;

Tortell et al., 2014; *Tortell et al.*, 2011; *Ulfsbo et al.*, 2014]. The continuous and

simultaneous collection of underway measurements of dissolved gases, chlorophyll

fluorescence and physical ocean properties (e.g. temperature and salinity) allows us to

examine the relationship between physical and biogeochemical tracers. The high

temporal resolution of these continuous underway measurements also resolves variability

from the submesoscale (~1-10km) and mesoscale (~10-100km) to the basin scale.

116 *1.2 A conceptual framework relating productivity, export and chlorophyll*

117 The time rate of change of phytoplankton biomass is given by a balance between gross

118 primary production and loss from grazing and export:

119
$$\frac{\partial P}{\partial t} = GPP - (R_{PHY} + R_{HET}) - export \qquad (2)$$

120 where P is phytoplankton biomass (mmol C m^{-3}), GPP is the gross primary production

121 (mmol C m^{-3} day^{-1}), R_{PHY} is the phytoplankton respiration rate (mmol C m^{-3} day^{-1}) and

122 R_{HET} is respiration due to heterotrophy (mmol C m^{-3} day^{-1}). Phytoplankton biomass, P,

123 can be related to CHL, which is more routinely measured, to derive an evolution equation

124 for CHL:

125
$$\frac{\partial CHL}{\partial t} = [CHL:C][\mu(N, T, I) - R_{PHY}(T) - g(Z)]P - w_{bio}\frac{\partial P}{\partial z} \qquad (3)$$

126 where CHL is related to P via C:CHL, the ratio of phytoplankton carbon (C) to CHL; μ is

127 the phytoplankton growth rate (day^{-1}), which varies as a function of nutrient

128 concentrations (N), temperature (T) and light (I); g(Z) is the zooplankton grazing rate

129 (mmol C m^{-3} day^{-1}); and w_{bio} (m d^{-1}) is the sinking rate of phytoplankton cells. Whereas

130 NCP represents the net sum of the rate processes that remove organic carbon from the

131 surface mixed layer, CHL is a proxy for phytoplankton biomass modulated by the C:CHL

132 ratio, also known to vary regionally and seasonally [e.g. *Westberry et al.*, 2016]. As a

133 result of the significant variations in CHL:C in time and space, estimating $\frac{\partial P}{\partial t}$ from $\frac{\partial CHL}{\partial t}$ is

134 subject to large uncertainties. Similarly, we might not expect CHL and NCP to vary in

135 concert as NCP represents a rate of change of phytoplankton biomass, while CHL is a

136 proxy for the biomass itself.

137

138 *1.3 Productivity and export in the Kuroshio Extension*

139 Western boundary current extensions are known to be regions of high open ocean

140 productivity and are hypothesized to be hotspots of carbon export. These regions are

141 characterized by both strong zonal currents and a strong density front. They are also

142 characterized by energetic mesoscale and submesoscale dynamics that have been

143 hypothesized to be strong drivers of primary production [*Mahadevan*, 2015] and export

144 [*Honda et al.*, 2018]. As a result of this multi-scale variability in time and space, western

145   boundary current regions present a particular challenge to making observations that

146   resolve key biogeochemical processes [*Henson et al.*, 2016; *Todd et al.*, 2019].

147

148   The Kuroshio Extension (KE) is the branch of the Kuroshio western boundary current in

149   the Pacific, which turns to the east after separating off the coast of Japan. The seasonal

150   cycle of primary productivity in the KE region is relatively well known at specific

151   locations from moored time series studies. These studies show similar annual net

152   primary production (NPP) rates, obtained by ^{13}C incubations, both to the south and to the

153   north of the main KE front based on data collected at Station S1 (30°N, 145°E) in the

154   subtropical gyre, and Station K2 (47°N, 160°E) and the Kyodo North Pacific Ocean

155   Time-Series (KNOT, 44°N, 155°E) in the subarctic gyre, though with higher summer and

156   fall NPP to the north and higher winter and spring NPP to the south [*Imai et al.*, 2002;

157   *Matsumoto et al.*, 2016]. Although local time series studies are an important tool for

158   characterizing ocean biogeochemical processes, including the dynamics of the biological

159   carbon pump, they cannot fully describe the spatial variability found in the most dynamic

160   ocean regions [*Henson et al.*, 2016], thus these pointwise estimates of productivity are

161   difficult to extrapolate to generate accurate regional estimates of productivity, limiting

162   their utility.

163

164   The Kuroshio and Kuroshio Extension have been shown to act as a large-scale subsurface

165   nutrient stream, supporting large lateral transports of nutrients within the upper

166   thermocline [*Guo et al.*, 2013; *Guo et al.*, 2012]. The Kuroshio Extension is effective in

167   transporting nutrients in part because of large volume transports, but also because frontal

168   and mesoscale dynamics are associated with eddy scale vertical motions that can result in

169   anomalously high subsurface nutrient concentrations compared to adjacent waters along

170   the same isopycnals [*Nagai and Clayton*, 2017]. This suggests that the Kuroshio nutrient

171   stream injects nutrients into the surface mixed layer. Using satellite measured sea level

172   anomalies (SLA) and satellite estimates of CHL, *Kouketsu et al.* [2015] showed a

173   negative correlation between SLA and CHL concentrations in the Kuroshio Extension

174   region, suggesting that higher CHL is associated with cyclonic eddies. They also showed

175   seasonal differences in the strength of the correlations between SLA and CHL,

176 suggesting seasonal dynamics in the coupling between mesoscale eddies and CHL.

177 However, *in situ* observational evidence that supports the role of mesoscale dynamics in

178 nutrient delivery is still limited [*Clayton et al.*, 2014; *Nagai and Clayton*, 2017].

179

180 Here we analyze underway O_2/Ar derived estimates of *in situ* NCP spanning the KE

181 region from three different seasons: May 2011, September 2011, and July 2012. We use

182 satellite SLA data to identify eddy activity along the cruise tracks allowing us to we

183 investigate the role of physical ocean dynamics in regional and seasonal variations in the

184 relationship between NCP, SLA and CHL. In addition, the high alongtrack resolution

185 allows us to examine the scales of variability and seasonal variations in NCP and surface

186 CHL and the potential role of mesoscale eddies in fueling NCP. Finally, we examine the

187 relationship between NCP and surface CHL and how this relationship varies by season.

188 We find large seasonal differences in the correlation between NCP and surface CHL and

189 show that they are strongly decoupled across all scales in spring when NCP is at its peak,

190 but strongly coupled in summer away from the KE jet. Finally, we use the conceptual

191 model in eqn. 3 to propose hypotheses for the observed (de)correlation in the

192 distributions and variability of NCP and CHL, suggesting a (de)coupling in the processes

193 controlling these quantities in the KE.
194

201

2. Data and Methods

In this study we define the Kuroshio Extension sub-region of the North Pacific as the area bounded by 140° - 170°E and 30° - 45°N, following the definition in [*Palevsky et al.*, 2016b]. We combine data from several sources, described in detail below, including data collected underway from ships of opportunity (Figure 1a), remote sensing, repeat hydrographic surveys, and Biogeochemical-Argo floats.

2.1 Underway and discrete sampling for O_2/Ar and CHL

We continuously measured O_2/Ar dissolved gas ratios, temperature, salinity, and fluorescence from an underway seawater system (10 m depth) during basin-wide transects of the North Pacific on the M/V OOCL Tokyo (May and September 2011) and the M/V OOCL Tianjin (July 2012). For each transect, the containerships transited through the KE sub-region within approximately a week, resulting in synoptic measurements. Temperature and salinity were measured using a Sea-Bird Electronics SBE45 thermosalinograph. Fluorescence was measured using a Seapoint Chlorophyll Fluorometer and calibrated to calculate underway chlorophyll-*a* concentrations for each cruise based on discrete samples collected from the underway seawater line every 6-8 hours and measured following standard methods on a Turner fluorometer [*Strickland and Parsons*, 1972].

Underway measurements of O_2/Ar dissolved gas ratios were made using continuous flow equilibrator inlet mass spectrometry (EIMS), following the method of [*Cassar et al.*, 2009]. Water from the underway seawater system was pumped into an equilibrator cartridge (Membrana MicroModule G569, 0.75" x 1"), the headspace of which was delivered to a quadrupole mass spectrometer (Pfeiffer Prisma QMS) that measured individual ion currents at one-second intervals. Ion current ratios for O_2/Ar are reported as the mean over a three-minute measurement period, chosen to match the e-folding response time for this EIMS setup. This yields a spatial resolution of ~2 km at the average ship speed of ~25 knots. Thus, both mesoscale and submesoscale features are resolved. For the September 2011 cruise, a Loess filter with a 30-minute half-span was applied to remove high frequency instrument noise, reducing the spatial resolution to ~40

9

233 km, giving a marginal sampling for mesoscale fields. This filter was not applied to the

234 May 2011 or July 2012 cruises in order to preserve the spatial resolution of the data.

235

236 Seawater dissolved gas O_2/Ar ion current ratios from the mass spectrometer were

237 calibrated by first correcting for instrument drift based on measurements of atmospheric

238 O_2/Ar (a known standard) sampled for 30 minutes every 3 hours, and second by

239 calibrating to discrete seawater samples collected every 6-8 hours and measured by IR-

240 MS (see *Palevsky et al.* [2016a] for details of the discrete sample measurement

241 procedures). The discrete sample calibration used a time-varying correction factor based

242 on the weighted mean of the individual correction factors determined from the three

243 nearest discrete samples. Uncertainty in the final corrected O_2/Ar EIMS measurements,

244 determined based on comparison with the discrete IR-MS measurements, ranged from

245 0.4% to 1.0% across the three cruises.

246

247 NCP was calculated from measured O_2/Ar dissolved gas ratios using a simplified mixed

248 layer mass balance budget. The calculation assumes that, other than the biological effects

249 on O_2 owing to photosynthesis and respiration that we aim to quantify in calculating

250 NCP, air-sea gas exchange is the primary additional influence on mixed layer O_2 and Ar

251 concentrations.

252

253
$$\text{NCP} = k[O_2]_{eq} \left(\frac{(O_2/Ar)_{meas}}{(O_2/Ar)_{eq}} - 1 \right) \tag{4}$$

254

255 The subscript "meas" represents the measured values and the subscript "eq" represents

256 the temperature- and salinity-dependent concentrations of O_2 and Ar expected if the

257 mixed layer were in equilibrium with the atmosphere, calculated from the solubility of

258 both gases [*Garcia and Gordon*, 1992; *R Hamme and Emerson*, 2004]. *k* represents the

259 wind speed-dependent air-sea gas transfer velocity, calculated from daily wind speed data

260 from the NOAA National Climatic Data Center's multiple-satellite Blended Sea Winds

261 product (https://www.ncdc.noaa.gov/oa/rsad/air-sea/seawinds.html) following the

262 *Nightingale et al.* [2000] equation and the *Reuer et al.* [2007] time-dependent weighting

263 scheme. Final NCP values are converted to carbon units using an O_2: C photosynthetic

264 quotient of 1.4 [*Laws*, 1991]. Mean uncertainty in calculated NCP is 4.6 ± 2.3 mol C m^{-2}

265 d^{-1}, determined by a Monte Carlo error analysis incorporating cruise-specific O$_2$/Ar

266 measurement uncertainty and 14% uncertainty in the gas transfer velocity (as determined

267 by *Palevsky et al.* [2016a]).

268

269 We omit from the mass balance budget additional terms accounting for physical

270 advection, mixing, and transient changes due to non-steady state conditions over the

271 dissolved gas residence time in the mixed layer. Although these processes can

272 significantly influence the mixed layer O$_2$/Ar budget in cases with strong vertical

273 exchange or deviations from steady state [*Jonsson et al.*, 2013], previous analysis of the

274 mixed layer O$_2$/Ar budget over the seasonal cycle in the Kuroshio region of the North

275 Pacific has shown that these influences are minimal during the period from springtime

276 restratification through fall, the seasons chosen for analysis in this study [*Palevsky et al.*,

277 2016a].

278

279 ***2.2 Sea Level Anomaly data***

280 In order to identify the location of the KE front and associated mesoscale eddies, we used

281 $1/4° \times 1/4°$ gridded daily sea level anomaly product that merges the data from multiple

282 satellites to obtain a high-solution view of the dynamics of the upper ocean (the

283 Ssalto/Duacs altimeter products produced and distributed by the Copernicus Marine and

284 Environment Monitoring Service, CMEMS). Closed contours of sea level anomaly that

285 enclose a hill/depression of sea level indicate the location of an anti-cyclonic/cyclonic

286 (clockwise/anti-clockwise) eddy. There is an associated anomaly in thermocline depth

287 that mirrors the SLA. For each cruise, we determined the date at which the cruise track

288 crossed the KE front and used the SLA data for that day for our analysis of the linkages

289 between NCP, CHL and SLA. For the May 2011, September 2011 and July 2012 cruises,

290 we used SLA data obtained on 19/05/2011, 23/09/2011 and 27/02/2012, respectively. The

291 container ships collecting the underway data crossed the region of interest within a 4- to

292 5-day period and we did not find any large changes in SLA within that time frame. In

293 order to compare the higher resolution underway data to the satellite data, we binned and

294 averaged the underway data into each of the 1/4° x 1/4° SLA grid cells coinciding with

295 the ship tracks.

296

297 *2.3 Nitrate data*

298 Samples for dissolved nutrient analyses were collected from the underway seawater line

299 at roughly the same frequency as the CHL samples, every 6-8 hours. These samples were

300 analyzed at the University of Washington Marine Chemistry Laboratory using standard

301 methods [*Intergovernmental Oceanography Commission*, 1994]. Although nutrient

302 samples were collected at the surface concurrently with the NCP and CHL data, these

303 data do not provide any information on the vertical structure of the nutrient fields in the

304 KE. The depth of the nutricline has been shown to vary considerably across the KE front

305 [*Clayton et al.*, 2014; *Nagai and Clayton*, 2017] and this is likely to be an important

306 control on vertical nutrient fluxes within the KE region. In order to understand possible

307 links between vertical nutrient fluxes and CHL and NCP, we make use of a range of

308 available, vertically resolved, *in situ* data collected between 2010 and 2017. This includes

309 data collected by Biogeochemical-Argo floats and Japan Meteorological Association

310 (JMA) repeat sections within the KE region in the period before and after our cruises.

311 The Biogeochemical-Argo nitrate data was downloaded directly from the MBARI

312 Chemical Sensor Group's FloatViz page (http://www.mbari.org/science/upper-ocean-

313 systems/chemical-sensor-group/floatviz/), and was comprised of measurements made by

314 two BGC-Argo floats, 7546 and 7674, both equipped with nitrate sensors and deployed in

315 the KE region in March 2013. Float 7564 and float 7674 continued collecting data until

316 early March 2017 and early January 2017, respectively. Only data from the floats flagged

317 as "good" was used in our analysis. In addition, we used data from the following JMA

318 cruises: 10-07 (October 2010), 11-08 (July – August 2011), 11-09 (September 2011), 12-

319 03 (April - May 2012), 12-05 (June – July 2012), 12-06 (July – September 2012), 13-04

320 (April – May 2013), 14-04 (April – May 2014), 15-04 (April – May 2015), 16-04 (April

321 – May 2016). Data from all of the JMA cruises are publicly available from the JMA data

322 portal (http://www.data.jma.go.jp/gmd/kaiyou/db/vessel_obs/data-

323 report/html/ship/ship_e.php).

324

325   During our study period, the KE took a zonal path, and was in its stable mode with no

326   large-scale meander (e. g. Figure 3; *Qiu et al.* [2014]). The nitrate data from the sources

327   listed above also corresponded to the KE's stable mode, thus allowing us to use that data

328   to construct a composite section of the vertical structure of nitrate across the KE front.

329   We excluded data collected during winter months (November, December, January and

330   February) when the surface nutrient signals can be driven by deep winter mixing [*Wong*

331   *et al.*, 2002]. Finally, we restricted the analysis to the top 150m of the water column in

332   order to capture the spatial patterns in nitrate within the surface mixed layer and the top

333   of the nutricline crossing the KE front.

334

335   *2.4 Assessing spatial variability*

336   Spatial variability for temperature, CHL and NCP from the May 2011 and July 2012

337   cruises was determined through a wavenumber Fourier transform. Because of the large

338   instrument noise in the September 2011 cruise data, the data was not of high enough

339   quality to determine variability at scales below ~80km, so it was excluded from this part

340   of the analysis. The container ships maintained a relatively steady speed along the tracks,

341   so the data are uniformly distributed in space, and we linearly interpolate the data onto a

342   regular 2 km track. In order to focus on submesoscale and mesoscale variability, we split

343   the data from each cruise into 500km overlapping segments, with 50 % overlap between

344   adjacent segments. We then removed the linear trend from each segment and applied a

345   Hanning window before performing the Fourier analysis. We normalized and averaged

346   the spectra for all of the segments to obtain the mean spectrum for each full cruise track.

347   We determine the 95% confidence interval in the spectra using the χ^2 distribution. The

348   slope of the spectra, in the 5-20km and 20-200km wavelength ranges, is estimated by

349   applying a linear regression to the log power spectral density estimates against the log of
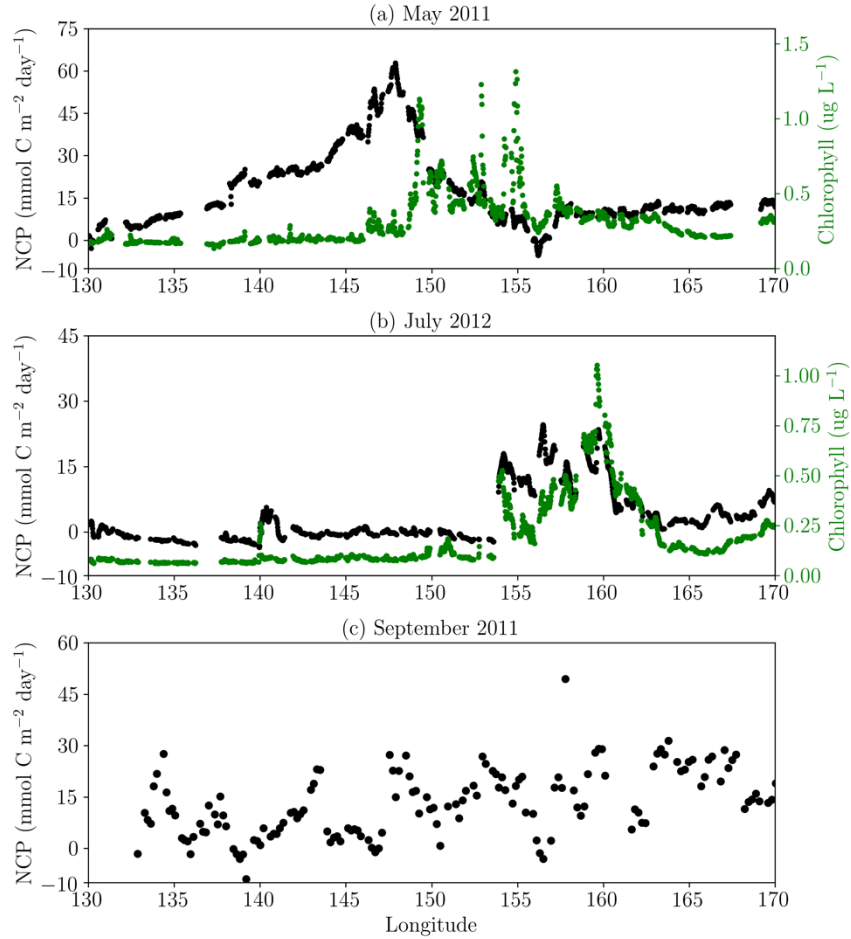

350   the wavelengths.

351

352

353

Figure 2. Underway surface estimates of NCP (mmol C m^{-2} d^{-1}) and surface CHL (μg L^{-1}), when available, for the (a) May 2011, (b) July 2012 and, (c) September 2011 cruises.

3. Results and Discussion

3.1. Physical setting and observed distributions of NCP and CHL

Each of the three container ship transects crossed the KE axis, with the May and September 2011 tracks both crossing the KE at approximately 145°E (Fig. 1a). The July 2012 transect was offset and crossed the Kuroshio front closer to the coast of Japan, largely bypassing the KE jet. Since the KE was in its stable mode with a shorter path length, a more northerly path, and relatively fewer mesoscale eddies [*Qiu et al.*, 2014], during the study period (May 2011 – July 2012), differences between May and September should be largely driven by seasonality, rather than differences in the level of mesoscale eddy activity. However, the transect in July was mostly to the north of the KE

14

369 axis. Although we do not have direct estimates of the mixed layer depth for our study

370 period, we calculated the mean MLD over the study region from the Monthly Isopycnal

371 & Mixed-layer Ocean Climatology (MIMOC; *Schmidtko et al.* [2013], Fig. 1b). The

372 mean climatological MLDs over the study region are: 28.65 +/- 6.3 m, 17.46 +/- 2.2 m

373 and 23.51 +/- 4.0 m in May, July and September, respectively with the uncertainty

374 reflecting the variability across the region. From June to August, the MLDs are at their

375 shallowest, while in May and September the MLDs are slightly deeper.

376

377 **Table 1.** Summary statistics for NCP (mmol C m^{-2} d^{-1}) and CHL (μg L^{-1}) data.

Figure 3. Daily maps of SLA with NCP overlain for the (a) May 2011, (b) July 2012 and, (c) September 2011 cruises. The mean dynamic topography is also indicated by black contour lines on each panel.

3.2 Correlations with SLA: influence of mesoscale processes on NCP and CHL

The correlation between SLA and NCP or CHL gives an indication of the importance of

mesoscale features (particularly eddies) in driving the observed distributions of NCP and

CHL. We examined correlations between SLA and NCP for each of the cruises

individually (Table 2, Fig. 4). Overall, the highest NCP values are associated with low

SLA (cyclonic cold-core eddies), however we did not find a consistent negative

relationship between NCP and SLA as might be expected if NCP were suppressed when

16

392

393

Figure 4. The relationship between SLA and NCP for the (a) May 2011, (b) July 2012 and, (c) September 2011 cruises. Regression lines are plotted on (a) for T > 18°C (red line) and T < 18°C (blue line); and on (c) for all points (black line).

397

398   the thermocline is deep. We found no significant relationship between NCP and SLA in

399   the May 2011 data when analyzed over the full KE region. However, when the data was

400   split into two subsets from north and south of the axis of the KE front, defined by

401   temperatures greater than 18°C to the south and less than 18°C to the north, we found two

402   distinct NCP vs. SLA regimes. South of the KE axis, with SST > 18°C, we found a

403   moderate positive correlation between NCP and SLA (r = 0.44). North of the KE axis,

404   with SST < 18°C, we found a strong negative correlation between NCP and SLA (r = -

405   0.76). In the September 2011 data, we also found a moderate negative correlation

406   between NCP and SLA (r = -0.50) over the entire cruise track, spanning both sides of the

407   KE axis. For July 2012, where most of the data was collected to the north of the KE axis,

408   we found a moderate positive correlation between NCP and SLA (r = 0.47). We also

409   determined the correlation between CHL and SLA. In May 2011, we found a consistent

410   moderate negative correlation between CHL and SLA (r = -0.48) across the full cruise

411   track. In the July 2012 data, there was a moderate positive correlation between CHL and

412   SLA (r = 0.36). Although fluorescence data was also collected during the September

413   2011 cruise, the fluorometer dynamic range was insufficient to obtain a good calibration

414   with discrete samples, so we have excluded that data.

415

416   It is expected that cyclonic eddies, negative SLA features where the MLD and

417   thermocline shoals and the nutricline is brought closer to the surface, should drive

17

418 increased primary production and enhanced CHL concentrations. Indeed, previous

419 studies in the KE region have found negative correlations between SLA and satellite-

420 derived CHL estimates. *Kouketsu et al.* [2015] found consistently negative correlations

421 between SLA and CHL along and to the north of the KE main axis, but positive

422 correlations between SLA and CHL in the recirculation gyre to the south of the KE axis.

423 Some of our results are consistent with this previous work, however we also see positive

424 correlations between both NCP and CHL and SLA in the July 2012 data, and a positive

425 correlation between NCP and SLA in the warmer waters to the south of the KE axis in

426 the May 2011 data. The highest NCP values seen in the July 2012 data are found within a

427 region bounded by ~154°W and 165°W (Figure 3b), spanning roughly 600km of the

428 cruise track. The Rossby radius of deformation in this region is ~30km [*Chelton et al.*,

429 1998], so this high NCP feature is far too large scale to be associated with mesoscale

430 eddies. We also note that during the July 2012 cruise there was relatively low eddy

431 activity such that SLA is small and not coherent (Figure 3b), suggesting that the high

432 NCP north of the KE is related to the large scale circulation rather than mesoscale

433 activity, possibly owing to the eastward flowing Oyashio Current that may bring nutrient

434 coastal waters into the subarctic interior of the North Pacific [*Kono and Sato*, 2010].

435 This pathway is reflected by the mean SLA contours that originate near Hokkaido (the

436 northernmost island in Figure 1a).

437

438 **Table 2.** Pearson correlation coefficients (r-values) for NCP and CHL with respect to SLA, and
439 their respective p-values.
440

	Correlation coefficient	p-value
May 2011		
NCP	-0.11	0.38 (Not significant)
NCP (T>18°C)	0.44	< 0.05
NCP (T<18°C)	-0.76	< 0.05
CHL	-0.48	< 0.05
July 2012		
NCP	0.47	< 0.05
CHL	0.36	< 0.05
September 2011		
NCP	-0.50	< 0.05
CHL	--	--

441 While there is a negative correlation between SLA and CHL in the May 2011 data, the

442 NCP relationship to SLA is different north and south of the front (Fig. 4). South of the

443 KE axis, where CHL is high but NCP is relatively low (Figure 2a), the correlation

444 between SLA and NCP is positive (Fig. 4). Conversely, north of the KE axis CHL is

445 relatively low but NCP is high.
446

448 **Figure 5**. Normalised power spectral density (PSD) plotted against wavelength for NCP (blue),
449 chlorophyll (green) and sea surface temperature (red) from underway data for the (a) May 2011
450 and (b) July 2012 cruises. The shaded area on each spectrum represents the envelope of the 95%
451 confidence interval.

452

453 *3.3 Spectral slopes of NCP, CHL and SST: mesoscale and submesoscale variability*

454 We investigate the range and magnitude of spatial variability in temperature, CHL and

455 NCP for the May 2011 and July 2012 cruises (Fig. 5). The September 2011 cruise data

456 was excluded from this part of the analysis because the data was not of high enough

457 spatial resolution to examine variance in the (sub)mesoscale range. Here, we examine the

458 spectral slopes (α, the slope of log PSD vs. wavelength) for the mesoscale (20-200 km)

459 and submesoscale range (5-20 km), reported in Table 3. Flatter spectral slopes (lower

460 values of α) are diagnostic of higher variability at smaller wavelengths (smaller spatial

461 scales). We find that values of α in the mesoscale range for all three tracers are similar in

462 May and July. However, values of α in the submesoscale range in May and July diverge

463 strongly between the three tracers. In May 2011, NCP has a much flatter spectrum in the

19

464 submesoscale range (α_{NCP} = -1.81) than temperature (α_T = -3.70) or chlorophyll (α_{CHL} = -

465 4.01), indicating higher variability in NCP at smaller spatial scales. In the mesoscale

466 range, NCP and temperature have similar spectra (α_{NCP} = -2.52 and α_T = -2.63), but

467 chlorophyll has a much flatter spectrum (α_{CHL} = -1.66), indicating that chlorophyll has

468 more spatial variability in the mesoscale range. In July 2011, NCP has a much steeper

469 spectrum in the submesoscale range (α_{NCP} = -4.48) than temperature (α_T = -2.91) or

470 chlorophyll (α_{CHL} = -3.22). In the mesoscale range in July, all of the tracers have similar

471 spectral slopes (α_{NCP} = - 2.64, α_T = -2.36, and α_{CHL} = -2.05). These results suggest a

472 consistent decoupling between NCP and both temperature and chlorophyll within the

473 submesoscale range, with NCP having either much flatter or much steeper spectral slopes

474 (α_{NCP}) in May and July, respectively. However, NCP and temperature appear to be more

475 closely and consistently coupled in the mesoscale range, whereas chlorophyll consistently

476 has a flatter spectral slope than both NCP and temperature in the mesoscale range.

477

478 **Table 3.** Spectral slopes for temperature, NCP and chlorophyll from the May 2011 and July 2012
479 cruises, with their respective r-values (all fits have p-values < 0.05).
480

	5 – 20 km range		20 -200 km range	
	Slope (α)	**r-value**	**Slope (α)**	**r-value**
May 2011				
NCP	-1.81	-0.93	-2.52	-0.95
Temperature	-3.70	-0.97	-2.63	-0.98
Chlorophyll	-4.01	-0.95	-1.66	-0.92
July 2012				
NCP	-4.48	-0.97	-2.64	-0.97
Temperature	-2.91	-0.95	-2.36	-0.97
Chlorophyll	-3.22	-0.93	-2.05	-0.93

481

482 Previous work has shown that both the reaction time (τ) and the scale of injection of a

483 tracer can impact its spatial distribution, and therefore its spectral slope. Tracers with

484 longer reaction times can be mixed down to smaller scales by the flow field, so tend to

485 exhibit flatter spectral slopes [*Abraham*, 1998]. Additionally, the spatial scale of the

486 processes that control the injection of a tracer, and whether or not it is related to the flow

487 field also impacts its distribution. When the supply of a tracer is related to the structure of

488 the flow field (e.g. eddies supplying nutrients to fuel production), then the spectral slope

489 of the tracer tends to be flatter with more variance at fine scales [*Lévy and Klein*, 2004],

490   compared to when the tracer supply is uncorrelated with the flow field, in which case the

491   spectral slope is controlled by the reaction time of the tracer [*Bracco et al.*, 2009].

492

493   In interpreting the spectral slopes reported here in Table 3, we must take into account

494   fundamental differences in the controls on residence times of temperature, CHL, and

495   O_2/Ar-based NCP. Sea surface temperature is largely controlled by ocean-atmosphere

496   interactions and the thermal capacity of water, resulting in a residence time of ~30 days

497   for temperature. We estimate the residence time for CHL to be on the order of 1-3 days

498   given a characteristic phytoplankton cell doubling time of 1 day^{-1}. O_2/Ar-based NCP

499   integrates over the dissolved gas residence time in the mixed layer (calculated as

500   MLD/k). The mean dissolved gas residence times for study region for the May 2011 and

501   July 2012 cruises, based on climatological MLD values and *k* (calculated as described in

502   the Methods section), are 9.6 days and 4.4 days, respectively. Given these residence time

503   estimates, in the simplest case where we assume that circulation features have no impact

504   on tracer distributions, we might expect that NCP would always have a flatter slope than

505   CHL (which has a shorter residence time) and a steeper slope than temperature (which

506   has a longer residence time). However, we do not consistently observe these relationships

507   between the temperature, CHL, and NCP spectral slopes. This indicates that coherent

508   velocity structures in the flow field likely impact the spatial structure of the observed

509   distributions of CHL and NCP, and may be diagnostic of localized vertical exchanges

510   either injecting nutrients into or modifying the light field in the MLD, or localized areas

511   of subduction removing organic carbon from the surface. Seasonal differences in the

512   strength of submesoscale processes [*Rocha et al.*, 2016] might result in seasonal

513   differences in the magnitude of the vertical supply of nutrients into the surface ocean.

514   One interpretation of our results could be that there is a stronger submesoscale-driven

515   vertical nutrient supply in May, when the mixed-layer is deeper than in July. Similarly,

516   grazing will have an impact on both NCP and CHL variability, and heterotrophic

517   respiration will also impact NCP variability.

518

519   We cannot test these hypotheses directly with this dataset, but future research should be

520   designed to directly account for these processes. Understanding the individual and

521 combined effects of the gas residence time, nutrient inputs, grazing and coherent

522 structures in the flow field on NCP spatial variability would be an important step in better

523 constraining the impact of different processes on the observed temporal and spatial
524 distributions of NCP.

525

526

527 **Figure 6.** (a) Map of Biogeochemical-Argo and JMA profiles in the KE region from which
528 nitrate depth profiles were used to construct the binned averages in panel (b). (b) Bin-averaged
529 nitrate data in latitude vs. σ_t space. The data was limited to profiles made between April and
530 October from the top 100m, to limit the influence of higher nutrient values driven by winter
531 mixing.

532

533 *3.4 Influence of the Kuroshio Extension nutrient stream on NCP and CHL*

534 We examine the NCP data along with *in situ* nitrate data from Biogeochemical-Argo

535 floats and JMA repeat sections from the KE region to discern whether regions where we

536 would expect an enhanced supply of the nitrate to the euphotic zone due to the KE

537 nutrient stream also support higher NCP. Although this *in situ* nitrate data was collected

538 currently with the NCP measurements, the data is limited to a similar seasonal time range

539 to the NCP data (April – October). We bin the *in situ* nitrate data into σ_t vs. latitude bins

540 (Figure 6). We expect nitrate concentrations to be roughly constant along isopycnals, so a

541 positive nitrate anomaly along isopycnals in the vicinity of the KE frontal axis is

542 diagnostic of the nutrient stream. We find a positive anomaly in nitrate concentrations

543 between 33°N and 36.5°N, and between the 23.5 kg m^{-3} and 25.5 kg m^{-3} isopycnals with

544 respect to waters to the north and south (Figure 6). This confirms previous results based

545 on a much finer scale survey of the KE that also found a nitrate anomaly in the same

546 isopycnal range [*Nagai and Clayton*, 2017], within a 50km swath centered on the KE

22

547 axis. The main difference here is that we see the anomaly extending over a wider lateral

548 range. This is likely because we incorporate data from a larger meridional and latitudinal

549 range, spanning many months, whereas the previous survey took place over the course of

550 5 days over a much smaller region. The signature of the nutrient stream in our analysis of

551 the *in situ* nitrate data, albeit over a wider latitudinal range suggests that the stream is a

552 consistent feature of the KE that follows the KE axis as it moves meridionally. We

553 combine and bin the NCP and CHL data in the same way as for nitrate (Figure 7), using

554 CHL data from only the May 2011 and July 2012 cruises. We find that the highest CHL

555 values tend to be found in denser, more northerly waters, in a density range from 24 kg

556 m^{-3} to 26.5 kg m^{-3} and at latitudes north of 37°N. NCP has a different distribution, with

557 the highest NCP values found in a density range 23.5 kg m^{-3} to 26.5 kg m^{-3}, and a

558 latitudinal range from 35.5°N to 38.5°N. These elevated NCP values are found within a

559 similar density and latitude range to the KE nutrient stream.

560

561

Figure 7. Bin-averaged a) CHL (µg L^{-1}) from the May and July cruises, and b) NCP (mmol C m^{-2} d^{-1}) from the May, July and September cruises, in latitude vs. σ_t space (note that CHL is shown on a log$_{10}$ scale).

565

566 The overlap between the region of elevated NCP and the KE nutrient stream points to the

567 importance of localized lateral and vertical nutrient supply within the KE jet in driving

568 productivity in this region. However we do not find a similar overlap with the KE

569 nutrient stream in the CHL data. This mismatch may, in part, be due to the more

570 restricted set of CHL data skewing our results. However, annual climatologies of CHL in

571 this region show an increase with latitude, suggesting that even the data presented here is

572 capturing consistent large-scale regional patterns in CHL. This result supports the

573 hypothesis that NCP in the KE region is strongly controlled by both lateral and vertical

574 nutrient supply within the jet. We would also expect to see seasonally driven differences

575 in the coupling between CHL and NCP, and CHL and the nutrient stream. Future targeted

576 studies in the KE region, with concurrent NCP and vertically resolved nutrient data,

577 would make it possible to directly test this set of hypotheses.

578

579 *3.6 (De)coupling between CHL and NCP*

580 As mentioned above, one of the more striking results of this work is the strong seasonal

581 and regional shift in the relationship between NCP and CHL, and the changing of the

582 relationships of these variables to SLA. We see a strong decoupling between NCP and

583 CHL in the May 2011 data (Figure 2a), with essentially no correlation ($r = 0.01$; $p < 0.05$)

584 between NCP and CHL. In contrast, in the July data, NCP and CHL are very strongly

585 correlated ($r = 0.85$; $p < 0.05$). Previous studies with concurrent NCP and CHL

586 measurements have also found strong variations in the correlation between NCP and

587 CHL. In high latitude systems, strong correlations between NCP and CHL were observed

588 during the spring bloom [*Tortell and Long*, 2009], in summer [*Tortell et al.*, 2012], and

589 across a springtime productivity hotspot at the transition between the coastal and open

590 ocean [*Palevsky et al.*, 2013], but much weaker correlations after the peak of a bloom

591 [*Tortell et al.*, 2011]. Conversely, a study in the equatorial Pacific found no correlation at

592 all between NCP and CHL [*Stanley et al.*, 2010]. Previous studies have also demonstrated

593 spatial decoupling between NCP and export of particles from the mixed layer [*Estapa et*

594 *al.*, 2015], as well as 2-15 day temporal lags between peaks in surface CHL

595 concentrations and in export flux [*Stange et al.*, 2017].

596

597 Regions with high NCP but low CHL concentrations (such as the region north of the KE

598 axis in May 2011) could either reflect an early-phase bloom feature, where NCP is high

599 but biomass has not yet had sufficient time to accumulate and produce high CHL

600 concentrations, or could reflect an ecosystem where the majority of organic carbon

601 produced is quickly exported from the mixed layer rather than accumulating biomass in

602   the surface. Similarly, regions with low NCP but high CHL concentrations could either
603   reflect a senescent bloom phase, where biomass remains high but NCP has diminished
604   due to a rise in respiration or decrease in primary production. Regions with both high
605   NCP and high CHL (such as the region north of the KE axis in July 2012) could reflect
606   an ecosystem where the majority of organic matter produced remains suspended in the
607   mixed layer rather than being exported, or an ecosystem with high export along with
608   significant biomass accumulation, although this latter scenario is probably less likely.
609   Future efforts to disentangle these potential explanations would benefit from
610   measurements of export below the mixed layer, and of particulate organic carbon and
611   phytoplankton community composition, since large cells that sink more quickly out of the
612   mixed layer may be more likely to contribute to export than to surface biomass
613   accumulation.
614
615   Although our study provides high spatial-resolution data across the KE region, each
616   cruise provides only a snapshot view of the system. As a result we cannot resolve
617   transient temporal contexts (e.g. bloom stage) that might influence the observed
618   relationships between NCP and CHL. Additionally, the KE jet is a strongly advective
619   system, with current speeds $O(1 \text{ m s}^{-1})$. This combination of dynamic ecosystem
620   processes embedded within a strongly advective system likely plays an important role in
621   driving some portion of the observed decoupling between CHL and NCP.
622

623   **4. Conclusions**
624   In this study, we have investigated the distribution of O_2/Ar-derived NCP estimates in the
625   KE region with high resolution *in situ* underway data collected during spring, summer
626   and early fall. These observations reveal large spatial variability in NCP in the KE region
627   at all scales down to the submesoscale. We also find strong correlations between NCP
628   and SLA (a proxy for mesoscale eddies), but the sign of these correlations varies
629   seasonally and regionally. Several common threads emerge from our analysis. We find
630   that mesoscale dynamics consistently play an important role in modulating NCP. The KE
631   jet is a hotspot of NCP within the larger KE region, and high NCP is associated with the
632   same density and latitude range as the KE nutrient stream. Crucially, these observations

633   reveal the extent of fine scale synoptic variability in NCP within the KE region. This

634   spatial and temporal variability is lost in large-scale climatological studies, where the KE

635   region is subsumed within broader regional averaging. Resolving and understanding the

636   drivers of this variability is likely to be key in building a mechanistic understanding of

637   the range of factors controlling rates of NCP in the region, which ultimately will enable

638   better parameterizations of these processes in Earth System Models.

639

640   Our observations also highlight seasonal and regional (de)coupling between NCP and

641   CHL which may impact the accuracy of CHL-based estimates of productivity. Previous

642   comparison of geochemical NCP estimates and satellite algorithm-based NCP in the

643   North Pacific has shown that no single algorithm is applicable both in the subarctic and

644   subtropical gyres [*Palevsky et al.*, 2016b], confounding the ability to use these algorithms

645   to evaluate NCP across the Kuroshio Extension frontal region. Understanding the

646   mechanisms that control the degree of coupling between NCP and CHL will allow us not

647   only to better understand the processes controlling the biological carbon pump, but also

648   to better predict NCP from observations of CHL and ocean color.

649

650   Although the results of this work suggest several avenues for further study, all require the

651   development of methods for collecting sustained, high-resolution biogeochemical

652   measurements within such dynamic western boundary current regions [*Todd et al.*, 2019].

653   Underway measurements collected from ships of opportunity provide a means of

654   collecting data from repeat lines at high spatial resolution but are restricted to surface

655   waters. In order to develop a mechanistic understanding of the physical and biological

656   factors controlling NCP, it is key to observe not only the surface ocean, but also the

657   vertical structure of the mixed layer, the photic zone, and the nutricline. We believe that

658   the development and expansion of the Biogeochemical-Argo program [*Claustre et al.*,

659   2020; *Johnson et al.*, 2009] will be a key source of synoptic data on the vertical

660   biogeochemical structure of the ocean. This study highlights the power of combining data

661   collected from a range of observing platforms across different spatial and temporal ranges

662   to build a fuller picture of this system. Future studies combining underway

663   biogeochemical measurements from the ocean surface (e.g. ships of opportunity,

664   saildrones) with vertically resolved data derived from a range of platforms (e.g. floats,

665   gliders) will drive developments in our mechanistic understanding of how

666   biogeochemical processes in dynamic ocean regions are modulated by physical and

667   biological controls.
