Abstract

Different Earth orientation parameter time series are publicly available that typically arise from the combination of individual space geodetic technique solutions. The applied processing strategies and choices lead to systematically differing signal and noise characteristics particularly at the shortest periods between 2 and 8 days. We investigate the consequences of typical choices by introducing three experimental EOP solutions obtained from combinations at both normal equation processed by DGFI-TUM and BKG and observation level processed by ESA as part of an effort funded by ESA to develop an independent capacity for routine EOP processing and prediction in Europe. All results are benchmarked against geophysical model-based effective angular momentum functions processed by ESMGFZ. We find, that a combination at normal equation level that explicitly aligns a priori station coordinates to the ITRF2014 frequently outperforms the current IERS standard solution 14C04. A somewhat experimental combination at observation level that currently considers only GNSS and Sentinel-3A and -3B to realize space links, already provides very competitive accuracies for the equatorial components. For ΔUT1 , VLBI information is known to be critically important so that the results are currently worse than those obtained from other geodetic series. The low noise floor and smooth spectra obtained from the combination at observation level nevertheless underline the potential of this most rigorous combination approach so that further efforts to also include VLBI are strongly recommended.

1 Introduction

The orientation of the solid Earth with respect to the celestial reference frame needs to be precisely known for a number of applications including ground-based astrometric observations, communication with satellites including probes in deep space, and also global navigation satellite systems (GNSS) nowadays used for the positioning of sometimes rapidly and even autonomously moving objects on the ground or in the air. Space geodetic techniques such as GNSS at permanent stations, Very Long Baseline Interferometry (VLBI), Satellite Laser Ranging (SLR), or Doppler Orbitography and Radio-Positioning Integrated by Satellite (DORIS) provide information about time-variations in the position of the terrestrial pole (polar motion), the spin rate of the Earth as expressed by changes in length-of-day (ΔLOD), and the celestial pole offsets (nutations). Those five (time-variable) parameters are conventionally referred to as Earth Orientation Parameters (EOP).

Due to the advent of more precise sensors, denser measurement networks, and the availability of (at least partly) redundant observation techniques, the precision of space geodesy has improved over the most recent decades. Commonly, the available sensor data is combined into intra-technique EOP solutions in a least-squares sense to arrive at best possible solutions with minimal errors. A number of intra-technique EOP solutions is subsequently combined by various approaches to arrive at one single EOP time series. However, in view of the high internal precision of the individual techniques it becomes increasingly important to enforce consistency among the different techniques to avoid the introduction of spurious artifacts. This includes in particular all aspects of the realization of the terrestrial reference system. Similar attention should be devoted to geophysical background models required to process individual observations like, e.g., solar radiation pressure effects on individual satellites, or ocean tide models including ocean tidal loading that affect space geodetic observations in numerous and typically highly systematic ways. A more rigorous way for the combination of the individual space-geodetic technique solutions would be the combination at the normal equation (NEQ) level of the Gauss-Markov model before solving for EOP. Ideal from a theoretical perspective would be the combination at observation level using one single software with identical parametrizations and background models to invert the observations from all techniques at once. So far, no publicly available EOP time series is applying any of the latter two approaches.

71 Polar motion and ΔLOD are largely dominated by terrestrial processes associated
 72 with the re-distribution of masses of the near-surface geophysical fluids. Variations in
 73 ΔLOD are largely dominated by zonal tropospheric winds (Salstein, 1993), whereas at-
 74 mospheric surface pressure and ocean dynamics are rather equally important for the ex-
 75 citation of high-frequency polar motion variations (Ponte & Ali, 2002). On seasonal time-
 76 scales, large-scale variations in terrestrial water storage are dominant (Chen et al., 2012).
 77 On decadal-to-centennial periods, prominent contributors to polar motion are the low-
 78 frequency changes in the continental ice masses (Adhikari & Ivins, 2016), whereas ΔLOD
 79 is also affected by core-mantle coupling effects (Holme & De Viron, 2013).

80 The quality of available models of global geophysical fluids relevant for the exci-
 81 tation of Earth orientation changes has increased tremendously in the more recent past.
 82 Atmospheric reanalyses produced by Meteorological Services like the European Centre
 83 for Medium-Range Weather Forecasts (ECMWF) are now routinely available (Dee et al.,
 84 2011). Particularly the mass component estimates of ocean and land hydrosphere mod-
 85 els have benefited from the availability of time-variable gravity field obtained with the
 86 GRACE mission (Göttl et al., 2019; Śliwińska et al., 2020). We therefore consider it as
 87 a nowadays viable option to use a geophysical model data set as the reference against
 88 which different geodetic combination time series are compared. Moreover, typical error
 89 sources of geodetic space techniques – like dependencies of the solar radiation pressure
 90 modeling on the satellite’s beta angle (inclination of the orbital plane w.r.t. the eclip-
 91 tic) or spacecraft geometry – are not inherent in geophysical models, and therefore should
 92 become visible in such a comparison.

93 The paper is structured as follows: We collect three of the most commonly used
 94 EOP series that were calculated from a combination of different geodetic space techniques,
 95 and additionally introduce three experimental EOP combination series processed specifi-
 96 cally for this study within a project of the European Space Agency to improve EOP (Sec.
 97 2). Subsequently, we derive so-called geodetic excitation functions (GAM) out of the EOP
 98 that can be readily contrasted against geophysical effective angular momentum (EAM)
 99 functions (Sec. 3). Time series comparisons are provided in terms of root mean squared
 100 differences, Taylor plots, and explained variances for different frequency bands (Sec. 4).
 101 Since largest differences among the geodetic solutions are found for periods shorter than
 102 8 days, we specifically discuss spectra for those highest frequencies (Sec. 5). The paper
 103 closes with a discussion of the differences found in the geodetic solutions and some rec-
 104 ommendations for future improvements in the processing of combined geodetic EOP so-
 105 lutions.

106 For completeness, we note that the celestial pole offsets are largely governed by grav-
 107 itational attraction of different bodies of the solar system. Only a very tiny fraction of
 108 the nutation is caused by (seasonally modulated) diurnal tides in oceans and atmosphere
 109 that additionally deform the solid Earth by means of surface loading (Nastula & Śliwińska,
 110 2020). Albeit formally a part of the set of Earth Orientation Parameters, we entirely dis-
 111 regard celestial pole offsets in this study.

112 2 Selected EOP Time-Series

113 The Earth Orientation Center of the International Earth Rotation and Reference
 114 Systems Service (IERS) at Paris Observatory is the official provider (Bizouard et al., 2020)
 115 of daily estimates of polar motion and ΔUT1 , which is the difference between Univer-
 116 sal Time (UT1), as defined by the Earth’s rotation, and the Coordinated Universal Time
 117 (UTC) realized by a network of highly precise and stable atomic clocks. ΔLOD equals
 118 to the difference of consecutive UT1-UTC estimates.

119 **2.1 C04-08: IERS 08C04**

120 The combination solution IERS 08C04 aligned to the ITRF2008 (called C04-08 in
 121 the remainder of this paper) results from a combination of intra-technique EOP series ob-
 122 tained from GNSS, VLBI, SLR, and DORIS (Gambis & Bizouard, 2009). One or two
 123 representative series from each technique are considered for the pole coordinates. For ΔUT1 ,
 124 the whole set of VLBI series available from the International VLBI Service for Geodesy
 125 and Astrometry (IVS) is taken into account, because no space-geodetic techniques other
 126 than VLBI is able to determine ΔUT1 in an absolute sense.

127 The intra-technique EOP series entering into the combination are made compat-
 128 ible by re-scaling the formal uncertainties and by re-aligning to both the International
 129 Celestial Reference Frame (ICRF) and the International Terrestrial Reference Frame (ITRF).
 130 Pole coordinates are smoothed by Vondrak-Filtering (Vondrak, 1977) and are interpo-
 131 lated linearly to equidistant daily epochs. The trend of the ΔUT1 series derived from
 132 GNSS and SLR is aligned to the trend of ΔUT1 obtained from VLBI. The final series
 133 are again smoothed by Vondrák-Filtering to remove spurious variations likely introduced
 134 by the applied numerical procedures. Since C04-08 refers to the axis of the nowadays out-
 135 dated ITRF2008, a slow degradation of the overall accuracy can be expected in partic-
 136 ular for epochs in the year 2009 and later.

137 **2.2 C04-14: IERS 14C04**

138 The EOP combination procedure applied at Paris Observatory has been thoroughly
 139 upgraded to calculate a new series IERS 14C04 (Bizouard et al., 2017), called here C04-
 140 14. This EOP solution is re-aligned to the most recent ITRF, thereby also improving the
 141 numerical combination procedure by the introduction of more realistic weights for the
 142 intra-technique solutions. Pole coordinates of C04-14 are now consistent with ITRF2014,
 143 whereas nutation offsets and ΔUT1 are aligned to the ICRF2 and ICRF3 before and af-
 144 ter the year 2019, respectively. The series C04-14 has been reprocessed back until 1962
 145 and is officially recommended by the IERS. It is updated two times per week, with an
 146 average latency of about 30 days. Differences to the previous solution C04-08 are as large
 147 as 50 μas in polar motion and 5 μs in ΔUT1 , and are primarily related to the selected
 148 terrestrial reference frame.

149 **2.3 JPL-Comb2018**

150 Earth Orientation Parameters are also processed at the Jet Propulsion Laboratory
 151 (JPL) of the National Aeronautics and Space Administration (NASA) in a manner that
 152 is fully independent from IERS. The so-called Comb2018 solution utilizes tracking data
 153 from Lunar Laser Ranging (LLR), the Global Positioning Satellite System (GPS), VLBI,
 154 SLR and historic optical astrometric observations by means of a Kalman Filter approach
 155 (Ratcliff & Gross, 2019). Rotational variations caused by solid Earth (Yoder et al., 1981)
 156 and ocean tides (Kantha et al., 1998) were removed from the ΔUT1 values prior to the
 157 combination and added back subsequently for the Mf and Mm partial lines only.

158 As the individual space geodetic techniques might use their own realizations of the
 159 terrestrial reference system when solving for EOP, e.g. EOP(IGS) 00 P 03 for the GNSS
 160 solutions provided by the International GNSS Service (IGS), both bias-rate corrections
 161 and uncertainty scale factors were determined for each single-technique EOP time se-
 162 ries. Each individual series was compared to a combination of all other remaining series
 163 to estimate those parameters individually for each technique. The procedure was repeated
 164 iteratively until convergence among all considered single-technique solutions had been
 165 reached.

166 It should be noted that updates to this series are only published at irregular in-
 167 tervals, so that Comb2018 is not suited for routine applications. It is, however, very well

168 applicable to check the quality of routinely processed EOP like C04-08, C04-14, and the
 169 experiments introduced below.

170 **2.4 Experimental solutions by DGFI-TUM and BKG**

171 The European Space Agency (ESA) is currently working towards establishing an
 172 independent capacity for calculating EOP out of multiple space geodetic data products
 173 processed within its Navigation Support Office (OPS-GN) at the European Space Op-
 174 erations Center (ESOC). An external team is currently being tasked with the develop-
 175 ment of a new combination software suitable for routine EOP estimation and prediction.
 176 This group consists of scientists from Deutsches Geodätisches Forschungsinstitut (DGFI-
 177 TUM) at the Technical University of Munich, Federal Agency for Cartography and Geodesy
 178 (BKG), Chair of Satellite Geodesy at the Technical University of Munich, Research Group
 179 Advanced Geodesy at the Technical University of Vienna, and the Earth System Mod-
 180 elling group at the Helmholtz Centre Potsdam GFZ German Research Centre for Geo-
 181 sciences (ESMGFZ). The work is in particular based on previous experience gained at
 182 DGFI-TUM as an IERS ITRS Combination Center (Seitz et al., 2012), and at BKG which
 183 is operating the IVS Combination Center jointly together with DGFI-TUM (Bachmann
 184 et al., 2016).

185 All input data to the combination software is provided in terms of technique-specific
 186 NEQs given in the Solution-Independent Exchange Format (SINEX) by ESA with the
 187 exception of the VLBI solutions (BKG). Before combination, the technique-specific NEQs
 188 undergo a set of pre-processing steps. Whereas GNSS, SLR, and DORIS already con-
 189 tain EOP parametrized at noon epochs, the VLBI-based EOP need to be transformed
 190 from session midpoints to the nearest noon epochs. The functional model of the Δ LOD
 191 parameter in the GNSS NEQs is expanded in order to account for a potential Δ LOD
 192 bias. In this study, we apply a fixed correction value of $-20 \mu\text{s}$ which is based on an anal-
 193 ysis (w.r.t. C04-14) of the ESA ESOC GPS+GALILEO LOD time series between 2016
 194 and 2019. Daily GNSS NEQs and session-wise VLBI NEQs are then accumulated to weekly
 195 technique-specific NEQs in order to match the weekly resolution of SLR and DORIS. The
 196 TRF datum for all techniques is kept by fixing all station coordinates to their a priori
 197 values, which ensures consistency between the estimated EOP and the a priori reference
 198 frame (Belda et al., 2017).

199 The combination of the weekly technique-specific NEQs to a common weekly NEQ
 200 is performed by summing up all NEQs with equal weights. Thereby, all technique-specific
 201 EOP at noon epochs are stacked to combined EOP at noon epochs. Parametrized are
 202 pole offsets, pole rates, Δ UT1, and Δ LOD. Each daily set of EOP at noon is transformed
 203 to the respective day boundaries as a pair of midnight offsets at 0h and 24h UTC, tak-
 204 ing into account the effect of tidal deformation on the Earth’s rotation in the transfor-
 205 mation of Δ UT1 and Δ LOD according to the IERS Conventions (Petit & Luzum, 2010).
 206 As described in Chapt. 8.1 of the conventions, all periods from 5 days to 18.6 years are
 207 considered for regularization. Afterwards, the pole offsets and Δ UT1 at the day bound-
 208 aries between consecutive days are stacked. As VLBI is the only space-geodetic technique
 209 that allows for the direct observation of Δ UT1, this procedure ensures that gaps between
 210 VLBI sessions are bridged with Δ LOD information from the satellite techniques. Thus,
 211 the combined NEQ system is invertible without any further EOP constraints. After in-
 212 version, weekly solutions with full sets of EOPs at the day boundaries (eight different
 213 epochs) are obtained. A time series of consecutive daily EOP estimates is subsequently
 214 generated by stacking the EOP values at the week boundaries at solution level, i.e., by
 215 calculating a weighted mean of the estimates. With that software and general process-
 216 ing strategy, two different experiments are performed.

217 **2.5 Experiment E1: Combination at NEQ-Level**

218 For Experiment E1, we use NEQs of GNSS and SLR solutions processed at the Anal-
 219 ysis Center (AC) ESOC as regular contribution to the IGS, and to the International Laser
 220 Ranging Service (ILRS), respectively. In addition, 24-hour VLBI solutions are used from
 221 the IVS AC at DGFI-TUM, whereas VLBI Intensive solutions are taken from the IVS
 222 AC at BKG. Station coordinates as given in each intra-technique NEQ are not changed
 223 in this experiment. The main problem arising from this treatment of the routine prod-
 224 ucts “as is” is that the ITRF realization to which the coordinates are referred changes
 225 over time, so the results have to be taken with care. Moreover, the NEQs provided by
 226 the IAG services do not necessarily contain station coordinates that are fully consistent
 227 with the ITRF2014, as technique-specific realizations of this TRF are used.

228 **2.6 Experiment E2: Combination at NEQ-Level aligned to ITRF2014**

229 In order to improve the consistency of the datum definition across all techniques,
 230 in the second experiment (E2) the station coordinates from ITRF2014 stations have been
 231 transformed to the ITRF2014 datum in advance. This procedure reduces datum inconsis-
 232 tencies for all stations given in the ITRF2014, but introduces some inconsistencies within
 233 the networks between ITRF2014 and non-ITRF2014 stations. However, these inconsis-
 234 tencies remain neglectable in the beginning of the processed period as the vast major-
 235 ity of sites processed is contained in ITRF2014. Later on, the inconsistencies become more
 236 relevant, as more stations not considered in the ITRF2014 are added especially to the
 237 GNSS network. Apart from the transformation of the a priori values before fixing the
 238 station coordinates, the combination approaches of experiment E1 and E2 are identical.

239 **2.7 Experiment E3: Combination at Observation Level**

240 We hypothesize that consistency of the contributions from the different geodetic
 241 space-techniques is a key element to achieve a best-possible EOP accuracy. To achieve
 242 that goal, ESOC reprocessed archived observation data from the International Doris Ser-
 243 vice (IDS), IGS, and ILRS in a single homogenized solution (Otten et al., 2012). This
 244 approach allows for the most rigorous combination of IDS, ILRS, and IGS reference frames
 245 by using space-ties. ESA is aiming for combining all Space Geodetic Techniques on ob-
 246 servation level (GNSS, SLR, DORIS and VLBI). However, to understand the impact of
 247 the different observation types, the solution is carefully extended by adding only one new
 248 observation type at a time. The present EOP solution, named here experiment E3, uses
 249 only GNSS together with Sentinel-3A and Sentinel-3B as low Earth orbiters for this space
 250 link. Both GNSS and SLR observations to those satellites are considered. In view of a
 251 full set of EOPs, it is especially important to mention that VLBI is missing in the ex-
 252 periment E3. Thus, $\Delta UT1$ cannot fully be determined.

253 **3 Effective Angular Momentum Functions**

254 Changes in the orientation of the solid Earth are conveniently studied by apply-
 255 ing the principle of conservation of angular momentum in the whole Earth system in-
 256 cluding its surrounding fluid layers. Relevant are both the instantaneous mass distribu-
 257 tion (matter terms) and the relative angular momentum changes associated to winds and
 258 currents (motion terms). Globally integrated angular momentum changes are multiplied
 259 with empirically derived parameters to account for the actual rheology of the Earth in-
 260 cluding, e.g. the anelasticity of the mantle, the partly de-coupled rotation of the core,
 261 and the associated equilibrium response of the oceans (Brzeziński, 1992; Gross, 2007).
 262 It is important to note that in contrast to EOP time series, EAMs are free of the dom-
 263 inating Chandler wobble in the equatorial components.

264 Globally integrated changes in angular momentum of each of the sub-systems can
 265 be described by effective angular momentum functions (EAM) derived from individual
 266 global numerical models. Customarily, those contributions are named as atmospheric an-
 267 gular momentum (AAM), oceanic angular momentum (OAM), and hydrological angu-
 268 lar momentum (HAM). The additional effect of a time-variable barystatic sea-level in
 269 response to a net-transfer of water mass from the land into the ocean is sometimes as-
 270 sumed to be part of the OAM, but sometimes also kept separated and labelled as sea-
 271 level angular momentum (SLAM).

272 3.1 ESMGFZ: Geophysical Model-Based EAM

273 The Earth System Modelling group at Deutsches GeoForschungsZentrum (ESMGFZ)
 274 routinely provides EAM describing the non-tidal geophysical excitations of Earth ori-
 275 entation changes due to mass redistribution in atmosphere, oceans, and the global wa-
 276 ter cycle. The data is based on re-analysis and operational analysis data from the Eu-
 277 ropean Centre for Medium-Range Weather Forecasts (ECMWF), ocean bottom pressure
 278 and vertically integrated ocean currents obtained from an experiment with the Max-Planck
 279 Institute for Meteorology Ocean Model (MPIOM) (Jungclaus et al., 2013), and terres-
 280 trial water storage and river flow velocities out of the Land Surface and Discharge Model
 281 (LSDM) (Dill, 2008). Both MPIOM and LSDM are consistently forced with ECMWF
 282 data. Please note that additional contributions arising from major earthquakes (Chao
 283 & Gross, 1995; Yun, 2019), electromagnetic jerks at the core-mantle boundary (Ron et
 284 al., 2019), or glacial processes in the continental ice-sheets (Mitrovica & Wahr, 2011) present
 285 in the geodetic observations are not covered by this model-based data-set.

286 The data is given in terms of dimensionless effective angular momentum functions
 287 of the matter and motion terms individually for all considered sub-systems. The tem-
 288 poral resolution ranges from 3 hours for atmosphere and oceans to 24 hours for the ter-
 289 restrial hydrosphere and sea-level terms. Tidal variations in atmosphere and oceans for
 290 the 12 most relevant frequencies are fitted and removed from the data in order to retain
 291 the non-tidal signals only. A long-term temporal mean was subtracted from all EAM com-
 292 ponents as estimated over the time-period 2003 – 2014 that approximately matches the
 293 length of one full solar cycle. The non-tidal EAM of ESMGFZ and their associated fore-
 294 casts are routinely updated every day. Further information on the product are provided
 295 via the web-page <http://esmdata.gfz-potsdam.de:8080/repository> and in the prod-
 296 uct description document (Dobslaw & Dill, 2018).

297 3.2 Geodetic Angular Momentum

298 To obtain excitation functions out of observed EOP, the Liouville equation

$$\dot{p} - i\sigma_c p = -i\sigma_c \chi, \quad (1)$$

299 with pole coordinates $p = p_1 + ip_2$ and complex Chandler frequency $\sigma_c = 2\pi(1 +$
 300 $i/2Q)/T_c$ is de-convoluted (Wilson & Vicente, 1990) to transform pole coordinates into
 301 so-called geodetic angular momentum functions (GAM) $\chi = \chi_1 + i\chi_2$. We use a Chan-
 302 dler period of $T_c = 434.2$ days with a damping of $Q = 100$, which is consistent with the
 303 parametrization of the rotational deformation applied in the model-based EAM calcu-
 304 lations. The axial component χ_3 follows from

$$\frac{d}{dt}(\text{UT1} - \text{UTC}) = -\Delta\text{LOD} = \chi_3 \cdot 86400 \quad (2)$$

305 GAM are available for every day since 1962. Those GAM should be therefore un-
 306 derstood as the excitation required to change Earth orientation in a way as it is observed

307 by space geodesy. Effects of long-period tides were removed from ΔLOD as recommended
 308 in the IERS conventions (Petit & Luzum, 2010) to make χ_3 comparable to the non-tidal
 309 EAM from ESMGFZ.

310 As an introductory example, we show time-series of GAM derived from Comb2018
 311 together with the sum of model-based EAM functions from ESMGFZ (Fig. 1). We note
 312 that model-based EAM explain almost 90 % of the intra-annual signal in χ_3 , which is
 313 related to the dominance of seasonal variations in zonal tropospheric winds that are very
 314 well captured by present-day atmospheric reanalyses. For the equatorial components,
 315 residuals are much larger (approximately 50 %) with both strong high-frequency vari-
 316 ability and a distinct long-term trend. The equatorial components are rather sensitive
 317 to mass distributions in polar regions with both strong variability in the wind-driven ocean
 318 dynamics and slow mass loss of ice-sheets and glaciers. Nevertheless, a considerable frac-
 319 tion of the signal seen by JPL-Comb2018 is explained by the model-based EAM so that
 320 it is sensible to use the geophysical model as a reference to evaluate the different geode-
 321 tic solutions.

322 4 Time Series Analysis

323 All GAM series calculated according to Sect. 3.2 from the EOP series introduced
 324 in Sect. 2 are available to us with daily sampling from January 2009 to April 2019. EAM
 325 are taken as sum of AAM, OAM (both sampled from 3h sampling to the daily epochs
 326 of GAM), HAM, and SLAM. A third-order Butterworth filter with varying cut-off pe-
 327 riods is applied to split all time-series into three frequency bands: (1) 2 – 8 days, (2) 8
 328 – 20 days, and (3) 20 – 100 days. In addition, also the (4) combined band of 2 – 100 days,
 329 and the (5) unfiltered series that includes all periods above 2 days are considered. We
 330 calculate various metrics commonly applied in time series analysis to quantify the cor-
 331 respondence of GAM and EAM. In particular, we use root mean squared differences (RMSD),
 332 standard deviations (STD), the Pearson correlation coefficient (CORR), and explained
 333 variances (EXVAR).

334 Root mean squared differences (RMSD) quantify the residual variability after sub-
 335 tracting ESMGFZ EAM from any of the GAM series, reduced by their mean offset over
 336 the analyzed period (Fig. 2). For the periods above 8 days, we find very consistent re-
 337 sults across the six GAM series considered. The only exception is the experiment E1,
 338 which has 5 % higher RMSD in χ_1 . Differences among the geodetic series are more pro-
 339 nounced at the highest frequencies: For the pole, E1 fits rather poorly to ESMGFZ when
 340 compared to the other solutions. For ΔLOD , both E1 and C04-08 have the largest mis-
 341 fit, whereas both experiments E2 and E3 are even slightly better than C04-14. In all com-
 342 ponents, JPL-Comb2018 provides the best fit to the model, and the largest margin with
 343 respect to the competing geodetic series is found in the third component.

344 To properly interpret the RMSD, it should be viewed in relation to the standard
 345 deviations of the two time series involved. It should be noted that the RMSD can be read-
 346 ily calculated from STDs and CORR according to

$$\text{RMSD}_{t,\text{ref}} = \text{STD}_t^2 + \text{STD}_{\text{ref}}^2 - 2 \cdot \text{STD}_t \cdot \text{STD}_{\text{ref}} \cdot \text{CORR}_{t,\text{ref}} \quad (3)$$

347 where indices t and ref denote the time series to be tested and the reference time
 348 series, respectively. That relation is utilized to display all three metrics jointly within
 349 a so-called Taylor diagram (Taylor, 2001). Those diagrams should be read by using the
 350 law of cosines where STD_{ref} and STD_t are the length of the sides of a triangle, and $\text{CORR}_{t,\text{ref}}$
 351 referring to the cosine of the angle between those sides. $\text{RMSD}_{t,\text{ref}}$ is the length of the
 352 third side of the triangle vis-à-vis to the correlation angle. Eq. 3 therefore provides a ge-
 353 ometrical relationship between the different metrics.

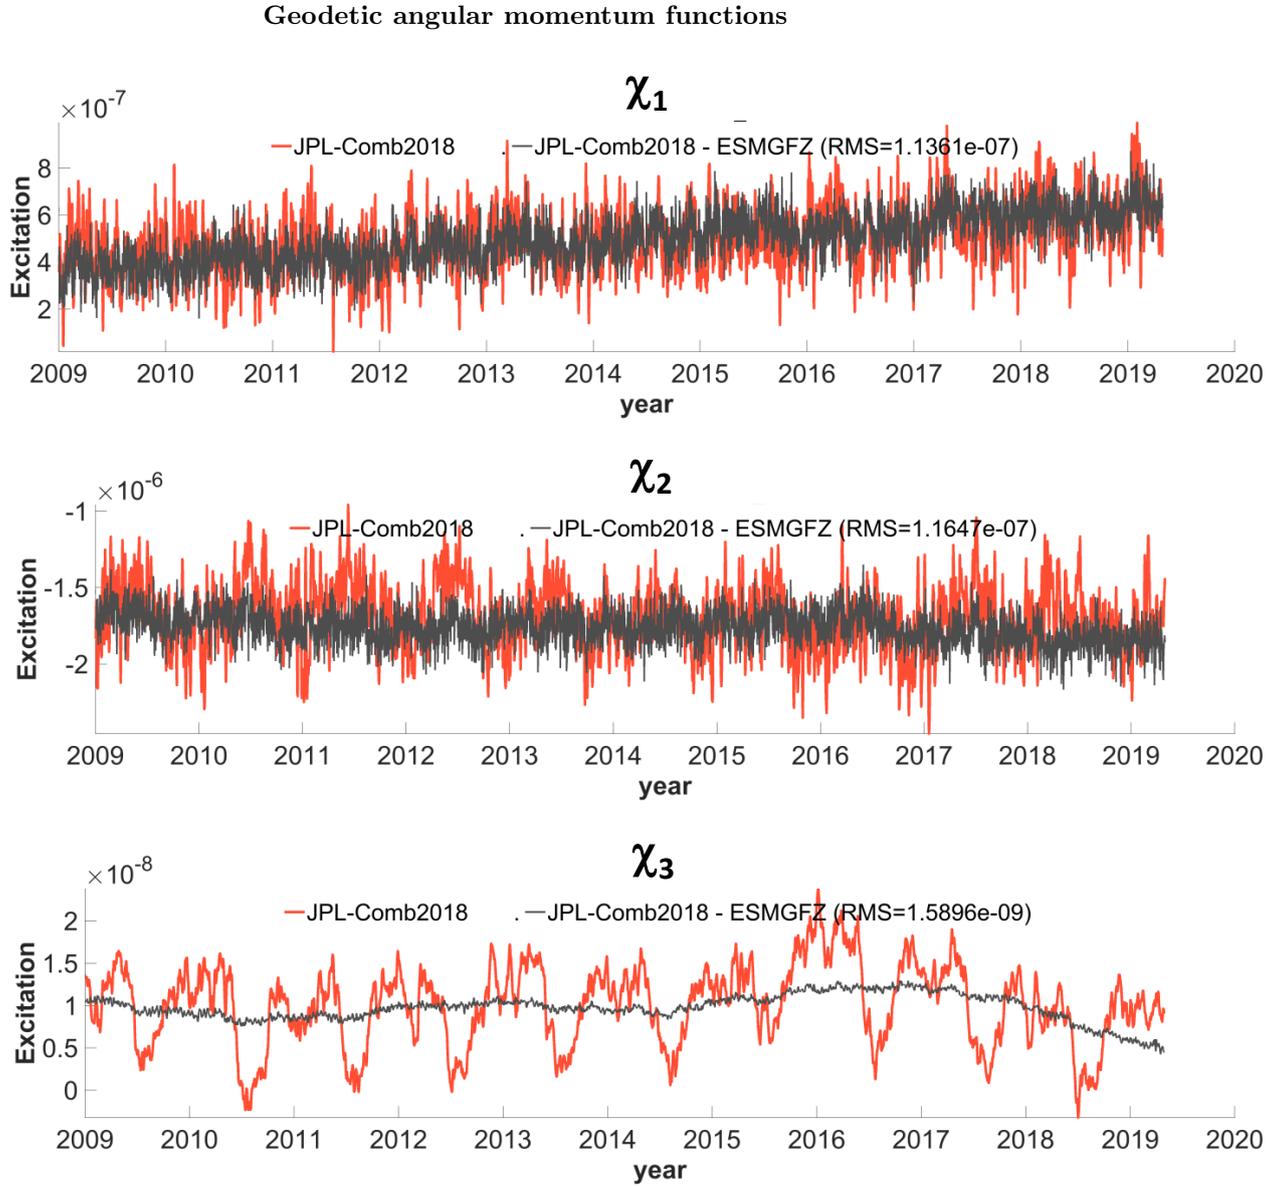

Figure 1. Geodetic angular momentum functions GAM from JPL-Comb2018 (red) and the residual after subtracting the model-based EAM from ESMGFZ (grey), for χ_1 (top), χ_2 (middle), and χ_3 (bottom). Excitation functions GAM and EAM are unitless.

Root mean squared differences (RMSD)

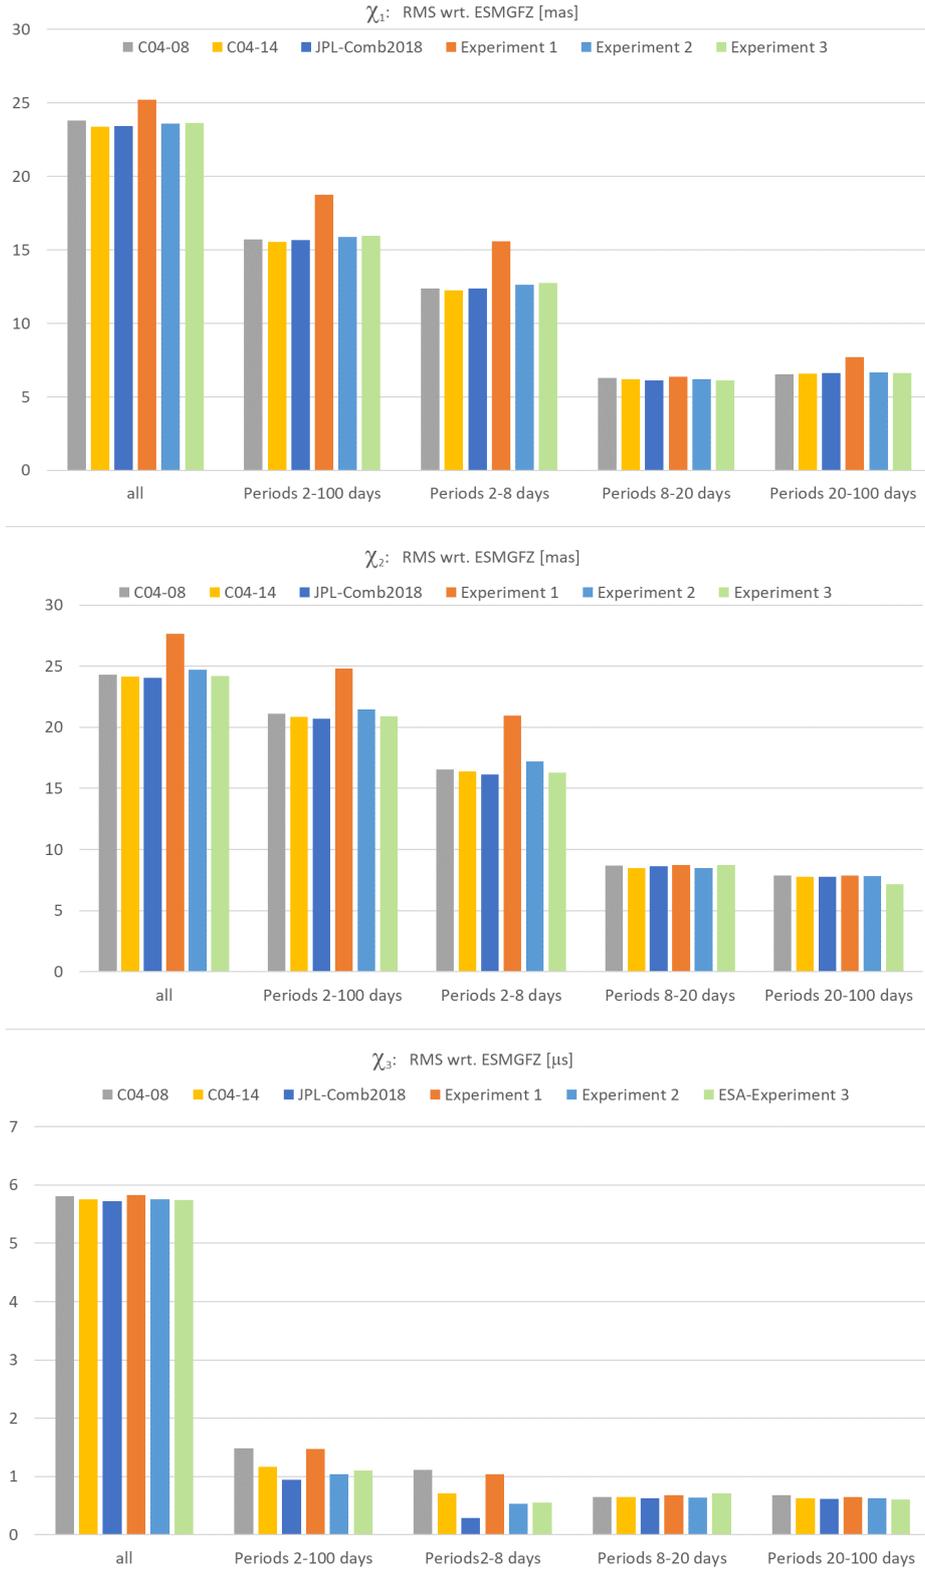

Figure 2. Root mean squared differences (RMSD) between geodetic angular momentum time-series GAM of different EOP solutions and the model-based EAM from ESMGFZ, for χ_1 (top), χ_2 (middle), and χ_3 (bottom). For better comparison, units are transformed into milliarcseconds [mas] for the equatorial components χ_1 and χ_2 , and in microseconds [μ s] for the axial component χ_3 .

354 In the following, we present Taylor diagrams that not only display results for the
 355 different GAM series (each by a separate color), but also for the different filters applied
 356 (each by a separate marker). For each category, the STD of the geophysical model-based
 357 time series ESMGFZ is given at the axis of abscissa as the reference point. The Euclidean
 358 distance from the reference point to the marker ($\text{STD}_t, \text{CORR}_t$) of an individual series
 359 gives the RMSD_t . Note that those RMSD values are equal to the values given in the bar
 360 plots of Fig. 2.

361 For both equatorial components (Fig. 3, top row), we generally find a good cor-
 362 respondence of all GAM series with the modelled EAM. Results for 20 – 100 days (stars)
 363 are very close to each other, and also the results for 8 – 20 days are quite similar for all
 364 six geodetic series considered. For the shortest periods below 8 days (squares), we find
 365 a substantially larger spread: C04-08 and C04-14 are still very close to each other, with
 366 slightly smaller RMSD and slightly higher correlation for the more recent series from IERS.
 367 JPL Comb18 has a notable smaller STD than C04, which nevertheless does not always
 368 lead to a smaller RMSD misfit. We also find a huge reduction in STD for E2 when com-
 369 pared to E1: since both experiments only differ in the treatment of the station coordi-
 370 nates (as given in the SINEX files for E1; taken from ITRF2014 where possible for E2),
 371 this result clearly underlines the importance of precise a priori coordinates for the de-
 372 termination of EOP.

373 We further note that experiment E3 always has the smallest STD from all geode-
 374 tic time-series considered. We recall that VLBI and DORIS information is still not in-
 375 cluded in this experiment and emphasize that the setup of the combination at observa-
 376 tion level might not be final yet. We nevertheless note that correlation and also RMSD
 377 are already quite competitive with respect to the other geodetic series. This indicates
 378 that pole coordinates are indeed very well determined from GNSS and SLR information
 379 alone. It is important to recall the (relatively) good performance of E3 might arise from
 380 the fact that all geodetic solutions except E3 have to deal with different parametriza-
 381 tions for the station positions adopted by the various Analysis and Technique Center which
 382 have a direct impact on the EOP solutions (Bloßfeld et al., 2014). For completeness, we
 383 also present the results for the band 2 – 100 days (pluses) and the unfiltered series (dots).
 384 The results basically reflect the findings of the weekly band and do not need to be re-
 385 iterated here.

386 For the axial component (Fig. 3, bottom row), we find again very consistent re-
 387 sults across all geodetic series for the lower frequencies and significant scatter only for
 388 the shortest periods of 2 – 8 days. For this component, C04-14 is a substantial improve-
 389 ment over the older series C04-08 with much reduced STD of the series, leading to both
 390 a smaller RMSD and a higher CORR with the geophysical EAM. This improvement is
 391 mirrored by the difference between E1 and E2, highlighting again the importance of a
 392 consistent terrestrial reference frame for EOP estimation. E3 has again the smallest STD
 393 of all series considered, but CORR and RMSD are much worse than experiment E2, thereby
 394 strongly underlining the well-known importance of VLBI for the determination of $\Delta\text{UT}1$
 395 and consequently ΔLOD . The best results in this comparison are obtained with JPL-
 396 Comb2018, where a similarly small STD is connected with CORR and small RMSD, indi-
 397 cating that a good compromise has been found in this series to suppress high-frequency
 398 noise while retaining the relevant short-period signals. As for the equatorial components,
 399 the results for the other frequency bands are also included in the plots for completeness,
 400 but do not provide additional insights.

401 As an additional evaluation metric not captured by Taylor plots, we define the ex-
 402 plained variance (EXVAR) as

$$\text{EXVAR}_{t,\text{ref}} = 1 - \frac{\text{STD}_{\text{err}}^2}{\text{STD}_{\text{ref}}^2} \cdot 100\% \quad (4)$$

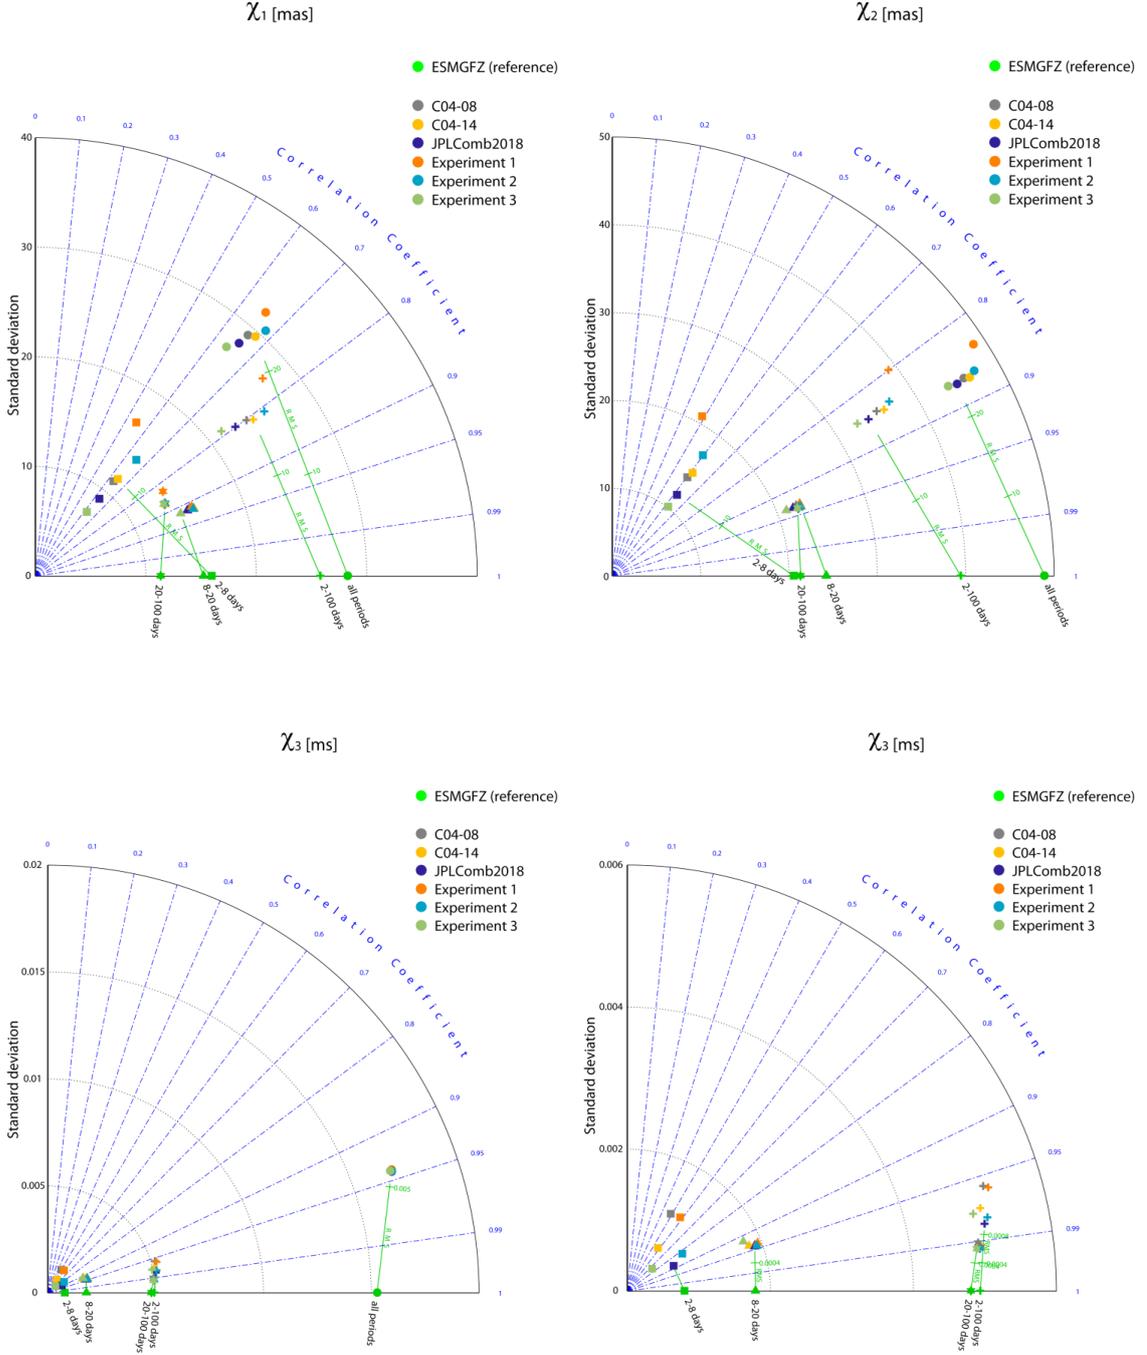

Taylor diagrams (STD-CORR-RMSD)

Figure 3. Standard deviation (STD) and correlation (CORR) of geodetic angular momentum time-series GAM derived from different EOP solutions compared to the model-based EAM of ESMGFZ for χ_1 (top-left), χ_2 (top-right), χ_3 for all frequency bands (bottom-left), and a zoom-in for χ_3 to standard deviations smaller than 0.006 ms (bottom-right). The mis-fit between GAM and EAM is given as root mean squared error RMSD by the distance between point of the GAM (STD/CORR) and the reference point for the EAM (STD/CORR=1). Different markers represent the results for 2 – 8 days (squares), 8 – 20 days (triangles), 20 – 100 days (stars), 2 – 100 days (pluses), and all periods (dots). For better comparison, units are transformed into milliarcseconds [mas] for the equatorial components χ_1 and χ_2 , and in microseconds [μ s] for the axial component χ_3 .

with STD_{err}^2 as the variance of the unexplained signal, that is the difference between the time series and its reference. Note that this quantity is also sometimes called coefficient of determination in the statistical literature. For identical time series, EXVAR equals 100 %, and for time series not fitting at all it might even become negative.

For the polar motion excitations χ_1 and χ_2 , EXVAR reaches values between 30 % and 75 % depending on the period band considered (Fig. 4). Differences among the six geodetic solutions are very small apart from the shortest periods between 2 and 8 days. Here, four series have a similar level of EXVAR for both χ_1 and χ_2 , whereas experiment E1 has very small and barely positive values only. As the a priori station coordinates were kept as given in the intra-technique NEQs and it is not mandatory that the technique-specific realizations of the terrestrial reference system are aligned to each other, station coordinates in E1 might differ among the techniques. Those differences in the station coordinates were eliminated in E2, which consequently does not contain anymore such spurious high frequency signals that almost entirely mask the real geophysical signal contained in the geodetic observations. Best results in this comparison are again obtained by JPL-Comb2018.

In the axial component χ_3 , the largest spread between the geodetic solutions is also found at the highest frequencies. C04-08 and E1 have largely negative explained variances. C04-14 and E2 reveal significant improvements, with E2 outperforming C04-14 by a substantial amount. It is interesting to note that the experiment E3 – the combination at observation level without VLBI information – is also already outperforming C04-14 and lags only slightly behind E2. The best performance, however, is found again with JPL-Comb2018.

5 Spectral Analysis

We calculate amplitude spectra for all GAM time-series and their residuals against the model-based EAM from ESMGFZ. For the longer periods of the equatorial components χ_1 and χ_2 , the residuals are dominated by a peak at 13.8 days not present in the EAM and possibly related to tidal aliasing. For the highest frequencies between 2 – 8 days, the spectra of the residuals against EAM differ substantially (Fig. 5, top and middle). We note very high variability and several significant peaks in both C04-08 and also E1. Those peaks somewhat reduce for C04-14 and E2, but remain much larger than in JPL-Comb2018, where the energy found at the highest frequencies is even lower than in the geophysical model. The experiment E3 instead has very little energy at the highest frequencies, which is between 2 and 3 days even smaller than in JPL-Comb2018. This is indeed interesting, since GNSS information with high temporal resolution has been ingested by the solution.

Results are quite similar also for the axial component χ_3 (Fig. 5, bottom). Prominent peaks are found in E1 and E2 at 7 days, which corresponds conspicuously to the chosen weekly NEQ accumulation interval. Less prominent peaks are also visible at the associated overtones of 3.5 and 2.3 days. A similar characteristic is also seen in C04-08, but disappeared almost entirely in C04-14. C04-14 suppresses high-frequency variations by a strong smoothing algorithm. JPL-Comb2018 and also E3 instead do not contain such prominent peaks. For the highest frequencies, JPL-Comb2018 and E2 are approximately at the same level as ESMGFZ. It should be noted, however, that VLBI 24-hour sessions are performed regularly twice a week (Mondays and Thursdays), which might contribute to the identified systematic. Moreover, no smoothing is applied in experiments E1 and E2. In contrast, the amplitude spectra of E3 calculated without any VLBI information at all reveals much smaller variability at those sub-weekly periods than predicted by the geophysical model, thereby clearly suggesting that important variability is not captured by the selected observing system configuration.

Explained Variances (EXVAR)

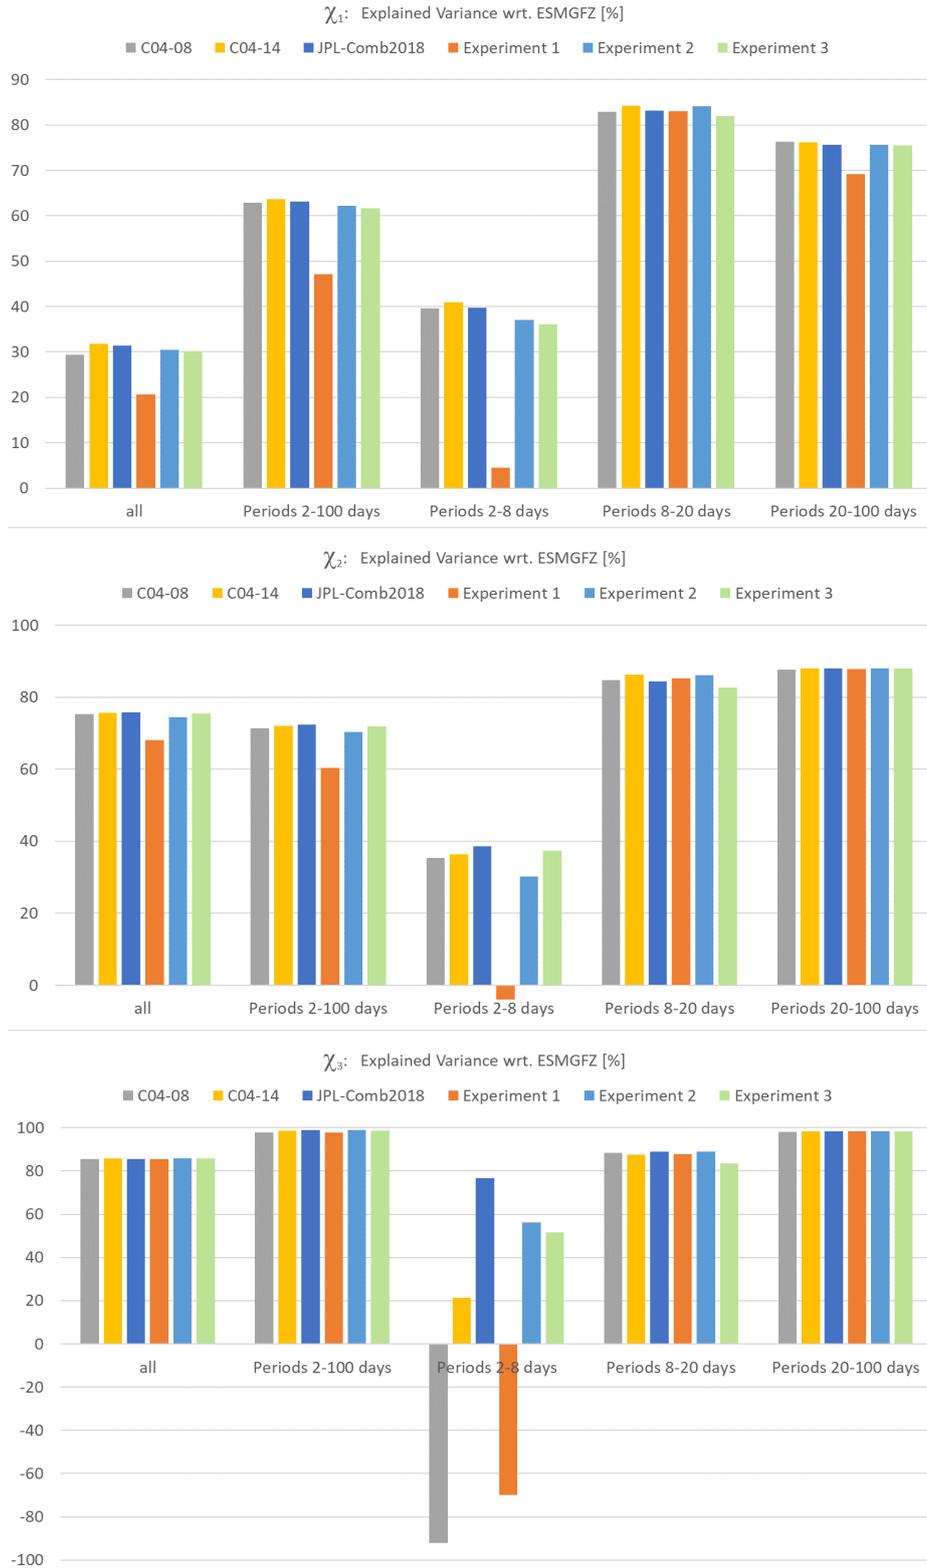

Figure 4. Explained variance (EXVAR) between geodetic angular momentum time-series GAM derived from different EOP solutions and model-based EAM from ESMGFZ, for χ_1 (top), χ_2 (middle), and χ_3 (bottom).

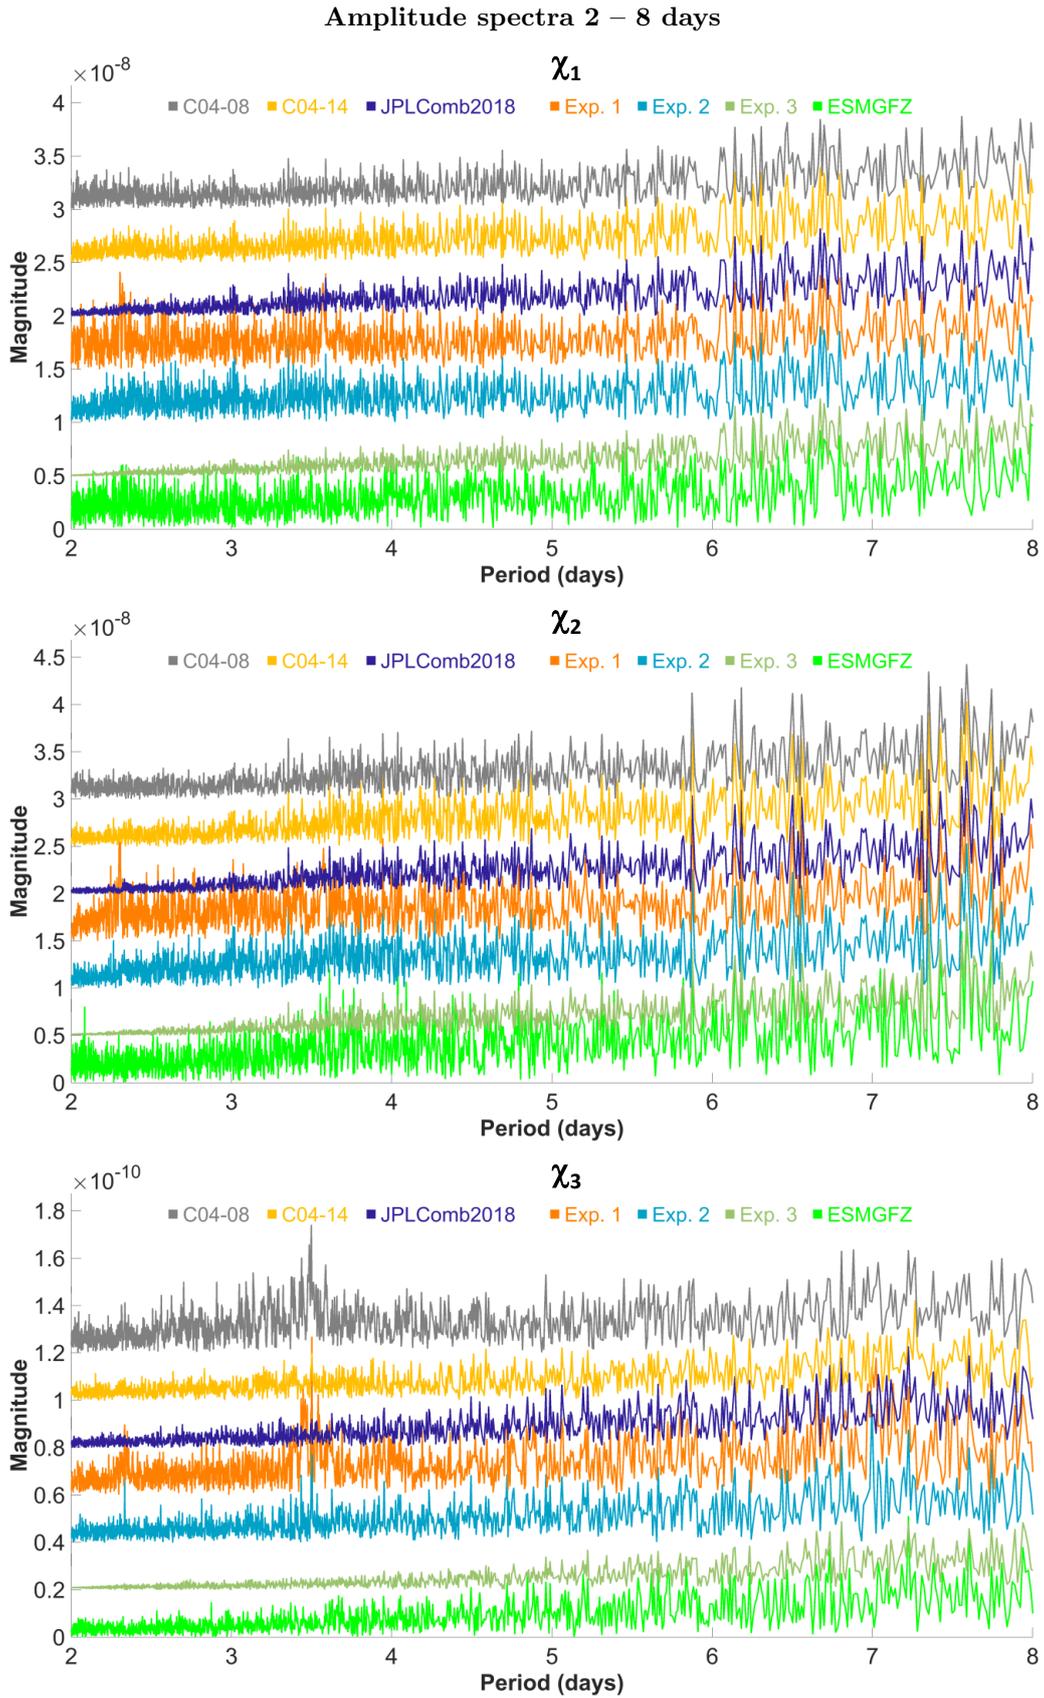

Figure 5. Amplitude spectrum of geodetic angular momentum time-series GAM derived from different EOP solutions and model-based EAM from ESMGFZ, for χ_1 , (top), χ_2 (middle), χ_3 (bottom). Excitation functions are unitless.

6 Summary and Conclusions

Three publicly available time series of terrestrial pole coordinates and Δ UT1 estimates are augmented by three experimental EOP series processed by DGFI-TUM and BKG and transformed into time series of geodetic angular momentum. All six geodetic series reveal very similar results for periods longer than a week, but show systematic differences among each other at periods between 2 and 8 days. We therefore conclude that individual processing choices during the geodetic data analysis significantly affect the resulting EOP, particular in the shortest periods.

A comparison against geophysical model-based excitation functions from ESMGFZ by means of various metrics (standard deviations, correlations, root mean squared differences, explained variances) documents the relative improvements achieved by the IERS with the transition from C04-08 to C04-14. The comparison also documents the superior quality of Comb18 processed at JPL, even though it has to be kept in mind that Comb18 is not updated routinely but instead processed at once for a fixed period of time. Comb18 therefore should be regarded as the target accuracy that should be aimed at with any EOP solution processed in an operational setting.

Three new experimental EOP solutions processed by DGFI-TUM and BKG in an operational setting agree well to the results obtained for the publicly available series. GAM from a combination of data from different geodetic space techniques at normal equation level that utilizes a priori coordinates as given in the SINEX files show spurious high-frequency signals and corresponding poor fits to the geophysical EAM. In the underlying EOP series the inconsistencies in the TRFs lead to high-frequency artifacts together with several jumps followed by short-lasting drifts that cannot be removed easily when combining EOP at the solution level. The quality of EOP obtained from a NEQ level combination drastically increases when a priori coordinates are harmonized to a consistent common reference frame. This solution generally even outperforms C04-14, thereby demonstrating that the operational setting with input data from independent sources combined at normal equation level, developed by DGFI-TUM and BKG, results in highly competitive EOP estimates. Furthermore, it demonstrates that a combination at normal equation level is preferable to a combination at parameter level.

From a theoretical perspective, a combination at observation level that utilizes space ties among the different geodetic techniques would be ideal for the processing of EOP. Available to us are preliminary results from a combination of Sentinel-3A and -3B with GNSS generated at ESOC. EOP from these solutions are characterized by exceptionally low noise at the highest frequencies which lead to the best fit with the geophysical model among all the operational geodetic series considered for the equatorial components. For the axial component, information from VLBI that is still missing in that solution leads to a degraded quality with respect to the results of a NEQ level combination (including VLBI R1-, R4-, and Intensive-sessions) with ITRF2014 a priori coordinates. Nevertheless, the achieved results for the pole are very promising, and efforts should be expedited to also include VLBI and other techniques into this solution type.

It should be emphasized that no additional smoothing has been applied to the EOP series specifically processed for this study. Spurious effects identified in either the time series or the spectral analysis as presented will now be analyzed further in order to identify possible causes for those artifacts. This might include the consequences of the selected accumulation length of 7 days; the regular schedule of the 24-hours sessions (which might be assessed by focusing on the epochs of the CONT campaigns, where significantly more VLBI data is available); or the impact of certain background model choices including the treatment of sub-daily tidal signals.

On a final note, the demonstrated ability to reliably identify consequences of individual processing choices on geodetic data products with the geophysical model-based

504 angular momentum functions demonstrate the tremendous improvement in accuracy in
505 those models achieved in the more recent past. For low frequency signals that allow for
506 the accumulation of geodetic observations over long periods of time and thus abundant
507 redundancy, geodetic estimates might be still safely regarded as a reference to bench-
508 mark numerical models against. For the higher frequencies with less observations and
509 a relatively higher impact of systematic errors, however, it would be prudent to evalu-
510 ate for each individual case if information readily provided by numerical models that in-
511 corporate information from various non-geodetic sources could be advantageously com-
512 bined with data from space geodesy to finally arrive at products with better external ac-
513 curacies.

521 able at <http://esmdata.gfz-potsdam.de:8080/repository>.

522 This study emerged from a project funded by ESA intended to develop an inde-
523 pendent capacity to routinely process Earth orientation parameters at OPS-GN of ESOC

524 (ESA contract no. 4000120430/17/D/SR). RD processed the ESMGFZ EAM functions,
 525 performed the comparative analysis, and wrote the first manuscript draft together with
 526 HD. AK, MB, and HH computed the experimental EOP time-series. FS, MT, and DT
 527 designed the study. ES initiated the study as the responsible ESA technical officer. All
 528 authors helped with interpreting the results and contributed to the final manuscript.
