12 **Key Points:**

13 • First assessment of natural spatio-temporal sediment dynamics in South America from
14 physically based model

15 • Floodplains anticipate the peak of suspended sediment discharge, and retain almost 12%
16 of sediments

17 • South America exports 2.76 Mt/day of suspended sediments to the oceans; 44%, 14% and
18 11% come from Amazon, Orinoco and La Plata rivers
19

20 **Abstract**

21 Suspended sediments (SS) contribute to the maintenance of several ecosystems. However,
22 intense soil erosion can lead to environmental, social, and economic impacts. South America
23 (SA) has very high erosion and sediment transport rates. Here we present a detailed description
24 of the spatio-temporal dynamics of natural SS flows in SA using the continental sediment model
25 MGB-SED AS. We evaluate the model with daily in-situ data from 595 stations, information
26 from regional studies and a global model. The model performance analysis showed that, in
27 general, there was a better agreement between simulated and observed data than with the
28 information found in regional studies and of the global model. The use of the hydrodynamic
29 propagation method has allowed a better representation of sediment flows in rivers and
30 floodplains. Based in the calibrated model results, SA delivers 1.00×10^9 t/year of SS to the
31 oceans, in which the Amazon (4.36×10^8 t/year), Orinoco (1.37×10^8 t/year), La Plata (1.11×10^8
32 t/year) and Magdalena (3.26×10^7) rivers are the main suppliers. The floodplains play an essential
33 role, retaining about 12% (2.40×10^8 t/year) of the SS loads reaching the rivers. In this study,
34 datasets related to SS flows in SA were generated and can be used to support other large-scale
35 researches or policymakers and stakeholders for adequate management of continental land use.
36 **Key words:** Continental-scale; Erosion; MUSLE; MGB

37

38 **1 Introduction**

39 Understanding erosion and sediment transport processes are relevant to comprehend geological
40 changes and landscape evolution (Latrubesse et al., 2005; Syvitski and Milliman, 2007; Zhang et
41 al., 2004), biogeochemical cycles (e.g., Beusen et al., 2005; Doetterl et al., 2012; Galy et al.,
42 2015; Ito, 2007; Kuhn et al., 2009; Lal, 2003; Müller-Nedebock and Chaplot, 2015; Naipal et al.,
43 2018; Tan et al., 2017; Van Oost et al., 2007; Willenbring and Von Blanckenburg, 2010), and
44 impacts of human activities, such as land use/ land cover changes (e.g., Murphy, 2019; Oliveira
45 et al., 2015; Panagos et al., 2017; Wang and Van Oost, 2019) and dams construction (e.g., Best,
46 2019; Cohen et al., 2014; Forsberg et al., 2017; García-Ruiz et al., 2015; Latrubesse et al., 2017,
47 2005; Restrepo et al., 2006; Syvitski et al., 2005). In the last 8,000 years, the conversion of
48 natural vegetation into agriculture has resulted in an accumulated erosion of about 27,187± 9,030
49 Gt worldwide (Wang and Van Oost, 2019). Meanwhile, it is estimated that the impact of soil
50 erosion on global GDP (Gross Domestic Product) is an annual loss of ~USS $8 billion,
51 threatening the food security, leading to a global reduction in the production of 33.7 Gt/year and
52 a consequent increase in water withdrawals of 48 billion m³/year (Sartori et al., 2019).

53 A large number of rivers with the largest sediment transports in the world (>100 Mt/year) are in
54 South America (SA, Borrelli et al., 2017; Doetterl et al., 2012; Latrubesse et al., 2005; Mouyen
55 et al., 2018; Naipal et al., 2018; Syvitski et al., 2014, 2005; Wuepper et al., 2019). The Amazon
56 River is at the top of the list (Latrubesse et al., 2005), transporting about 555 Mt/year at Óbidos
57 (Filizola and Guyot, 2009).. Borrelli et al. (2017) observed high erosion rates (>10 t/ha.year) in
58 SA in 2012, which increasing tendency compared to the 2001 year. This severe erosion has
59 contributed to generate, for example, a reduction in food production of 8,170 Mt/year in Brazil
60 (Sartori et al., 2019). Researches have shown that climate changes will impact the land use/ land
61 cover (Almagro et al., 2017; Brêda et al., 2020; Cohen et al., 2014) and that the implementation
62 of many dams will affect the connectivity of water flows even more, sediments, nutrients, and
63 aquatic organisms (Forsberg et al., 2017; Grill et al., 2019; Latrubesse et al., 2017).

64 In the last decades, great efforts have been dedicated to understanding and quantifying sediment
65 loads around the world. The use of in-situ measured data is one of the main tools used to
66 estimate the transport in rivers (e.g., Best, 2019; Dearing and Jones, 2003; Latrubesse et al.,
67 2005; Mouyen et al., 2018; Murphy, 2019; Niu et al., 2014; Restrepo et al., 2006) or watershed
68 erosion rates (e.g., García-Ruiz et al., 2015). However, there is a lack of measurements of
69 sediments in both intra-basin (e.g., García-Ruiz et al., 2015; Kettner et al., 2010; Lima et al.,
70 2005) and near the Oceans, where less than 10% of rivers have monitoring of sediment delivery
71 to coastal zones (Syvitski et al. 2005). Notably, in the era of big data and big science, there are
72 still a lack of hydrological, sediment, and nutrient data available in the world's large rivers (Best,
73 2019). The lack of data represents a major barrier to develop analyses for large scales
74 (continental or global) that require long time series (Dearing and Jones, 2003).

75 Computational sediment models have helped to fill this gap of sediment information. For the
76 global scale, several applications have been carried out with Universal Soil Loss Equation
77 (USLE, e.g., Xiong et al., 2019, 2018) – developed by Wischmeier and Smith (1978) – and its
78 revised version RUSLE (e.g., Borrelli et al., 2017; Naipal et al., 2018, 2015; Sartori et al., 2019;
79 Wuepper et al., 2019; Yang et al., 2003). According to Alewell et al. (2019), USLE and RUSLE
80 are the most used models around the world. However, approaches that used these models were
81 focused only on soil loss spatial representation, with long-term average estimates, which do not
82 allow to understand the dynamic processes that involve sediment flows, such as the loads
83 transported by the rivers. In this perspective, global sediment transport models were developed to
84 estimate the impact of human activities on sediment delivery to the oceans (Syvitski et al. 2005),
85 characterize rivers in terms of transported sediment loads (Cohen et al., 2013; Pelletier, 2012),
86 and assess regional trends and variabilities (Cohen et al. 2014). The global models are generally
87 empirically-based and have few input parameters, which facilitate applications on these scales.
88 Nevertheless, these models have been poorly validated, they were focused on estimating long-
89 term annual averages (e.g., Cohen et al. 2013; Pelletier 2012; Syvitski and Milliman 2007), and
90 are based on simplified methodologies to estimate hydrological variables and sediment routing.

91 Despite the barriers encountered in the model applications on a global scale, few papers are
92 found in the literature regarding continental scales. Panagos et al. (2015) used the RUSLE2015
93 model to estimate erosion rates for the reference year 2010 across Europe, with a spatial
94 resolution of 100 m. Campagnoli (2006) used an approach (not fully described) focused on
95 geological and geomorphological aspects to generate an annual sediment yield map of South
96 America. However, as mentioned in the previous paragraph, these approaches are not capable to
97 fully describe dynamic sediment processes.

98 The global model WBMsed used by Cohen et al. (2014) uses the simplified Muskingum-Cunge
99 routing method (Wisser et al., 2010). The global models of Pelletier (2012) and Syvitski and
100 Milliman (2007) do not explicitly consider the rivers flow routing. Studies performed in several
101 South America regions have shown that simplified methods are sometimes not suitable to
102 represent backwater and floodplain effects, which can be driving factors in flow routing in large
103 basins (e.g., Angarita et al., 2018; Bravo et al., 2012; Paiva et al., 2013, 2011; Pontes et al., 2017;
104 Siqueira et al., 2018; Zhao et al., 2017).

105 On the other hand, when we compare the sediment modeling studies with hydrological-
106 hydrodynamic modeling studies, one can see that significant advances have been made in the
107 later for global and continental scales. For example, studies made by Hanasaki et al. (2006),
108 Hanasaki et al., (2008a, 2008b) and Hanasaki et al. (2018) showed global scale simulations with

109   many capabilities to represent the global hydrological cycle and the human interference on it,
110   such as water abstractions and rivers impoundments. The van Beek et al. (2011) study used the
111   global PCR-GLOBWB model to evaluate water availability and water stress on a monthly scale
112   for the whole globe. Meanwhile, the study by Beck et al. (2017) shows how extensive global
113   hydrological models development research is, while evaluating the runoff estimates generated
114   across the globe by six global models in addition to four land surface models. Other examples,
115   with a greater focus on the fluvial hydrodynamic representation, are the studies of Yamazaki et
116   al. (2011) and Yamazaki et al. (2013), which showed global model applications for flooding
117   applications, including the impact of floodplains. Also, most of the models developed in recent
118   years simulate processes on a daily scale (Bierkens, 2015). Many of them have the concept of
119   "hyperresolution models" as their motivation, which aims to simulate processes on a global
120   scale, but whose results are useful on a local scale (e.g., Bates et al., 2018; Wada et al., 2014;
121   Wood et al., 2011).

122   On the continental scale, progress in the development of hydrological and hydrodynamic models
123   also stand out, with dam representation (Shin et al., 2019) and improvements in fluvial
124   hydrodynamics (Siqueira et al., 2018). The National Water Model (NWM,
125   http://water.noaa.gov/about/nwm) developed in 2016 by National Oceanic and Atmospheric
126   Administration (NOAA), which has been conducting simulations and streamflow forecasts for
127   the United States, can be mentioned as an example. The study of Siqueira et al. (2018) applied
128   for the first time a continental-scale fully coupled hydrological-hydrodynamic model for the
129   whole South America. The Siqueira et al. (2018) results showed that limitations on flow
130   estimation by state-of-the-art global models could be reduced using better calibrated continental
131   models, which represent relevant processes (e.g., hydrodynamics) for the area of interest, and
132   which are built on previous experience of regional-scale studies.

133   While these cited examples of hydrologic and hydrodynamic modeling with continental and
134   global scales have increasingly appeared in the literature, including the goal of attaining
135   "hyperresolution" models, no study has been found in the literature to estimate continental-scale
136   sediment transport having hydrologic-hydrodynamic processes integrated. There is then a gap
137   between the advances in large scale hydrologic and hydrodynamic modeling and the advances in
138   sediment modeling at continental and global scales.

139   Bridging the gaps between recent advances in hydrologic and hydrodynamic modeling at
140   continental scales and sediment modeling provide some opportunities: (i) obtain models that
141   allow the comprehension and comparison of spatial and temporal dynamics explicitly, and that
142   still represent important processes such as backwater effects in the rivers and the lateral flow
143   exchange of water and sediments with floodplains (e.g., Buarque, 2015; Cohen et al., 2013; Grill
144   et al., 2019; Paiva et al., 2013, 2011; Pontes et al., 2017; Rudorff et al., 2018); (ii) obtain
145   continental or global scale models that are well-validated to provide locally relevant information
146   at multiple time scales and suitable for policymakers and stakeholders (Bierkens, 2015;
147   Fleischmann et al., 2019b; Siqueira et al., 2018); (iii) acquire continental sediment discharges
148   information not only in the outlets of large rivers but also intra-basin. These items, therefore,
149   become the interest of this study, which has South America as a subject of study, and aims to
150   answer the following specific questions from modeling results: what is the accuracy of the
151   proposed continental sediment model? What are the potential transported loads by the rivers in
152   the continent? What are the spatial and temporal dynamics of sediment flows over South
153   America? What is the impact of fluvial hydrodynamics on sediment transport and deposition? In

154 which regions do suspended sediments deposit the most? To answer these questions, we have
155 developed and evaluated the performance of sediment erosion and transport model for the entire
156 South American domain.

157 **2 Overview of Sediment-Related Processes in South America**

158 South America (SA) transports ~20% of the sediments reaching the oceans (Syvitski et al.,
159 2005), and the Amazon and Magdalena rivers (Figure 1-a) are among the world's largest
160 sediment delivers (Mouyen et al., 2018). SA has the second-highest potential erosion rate on the
161 planet and the highest increase in the last century (Wuepper et al., 2019). This increase also
162 attributes to SA the highest rate of particulate organic carbon erosion. (Naipal et al., 2018).
163 Among the causes of these changes are agricultural expansion and deforestation (Borrelli et al.,
164 2017), which have been increasing, causing concerns in the Amazon basin (Aguiar et al., 2016;
165 Aragão, 2012).

166 Most of the SA is located in tropical regions that have little interannual variability between
167 sunrise and sunset and receive high solar incidence. The Intertropical Convergence Zone (ITCZ)
168 directly influences the establishment of dry and rainy seasons; El Niño events; and the South
169 Atlantic Convergence Zone (SACZ), which causes heavy precipitations in the summer. Annual
170 precipitation variability is strong, with desert regions in Chile and rainfall reaching
171 approximately 10,000 mm in Colombia (Latrubesse et al., 2005).

172 Rivers that drain the Andean region transport the highest sediment load on the continent.
173 According to Restrepo et al. (2006), the Magdalena River is the one with the highest average
174 sediment yield (690 t/km².year). More than 90% of the suspended sediment (SS) load of the
175 Amazon Basin comes from the Andes (Latrubesse et al., 2005). Filizola and Guyot (2011), using
176 in-situ measured data, indicate that the Madeira River (Figure 1-a) contributes almost 50% to the
177 Amazon River solid discharge, in which the Beni and Mamoré rivers represent about 72% and
178 28%, respectively, of the Madeira transport. (Guyot et al., 1999). The Ucayali River drains the
179 Peruvian Andean part and is also one of the SA rivers with the highest SS load (Latrubesse et al.,
180 2005). Rivers originating in the South Andean regions also carry high SS loads, such as the
181 Bermejo River, which provides about 90% (Amsler and Drago, 2009) and the Pilcomayo river
182 about 140 Mt/year of the total load carried by the Paraná River (Latrubesse et al., 2005). Lima et
183 al. (2005) observed that smaller rivers like Parnaíba, Paraíba do Sul and Doce (Figure 1-a),
184 although they do not have the highest sediment yield rates (t/year.km²), they have high values of
185 suspended sediment concentrations (SSC) (Lima et al. 2005). According to Latrubesse et al.
186 (2017), Cratonic rivers such as the Negro, Tapajós and Xingu present low SS loads. At the same
187 time, the Araguaia (Latrubesse et al., 2005), Tocantins (Latrubesse et al., 2005), Paraná (Amsler
188 and Prendes, 2000) and Orinoco (Meade et al., 1990) rivers have intermediate values of SS yield.
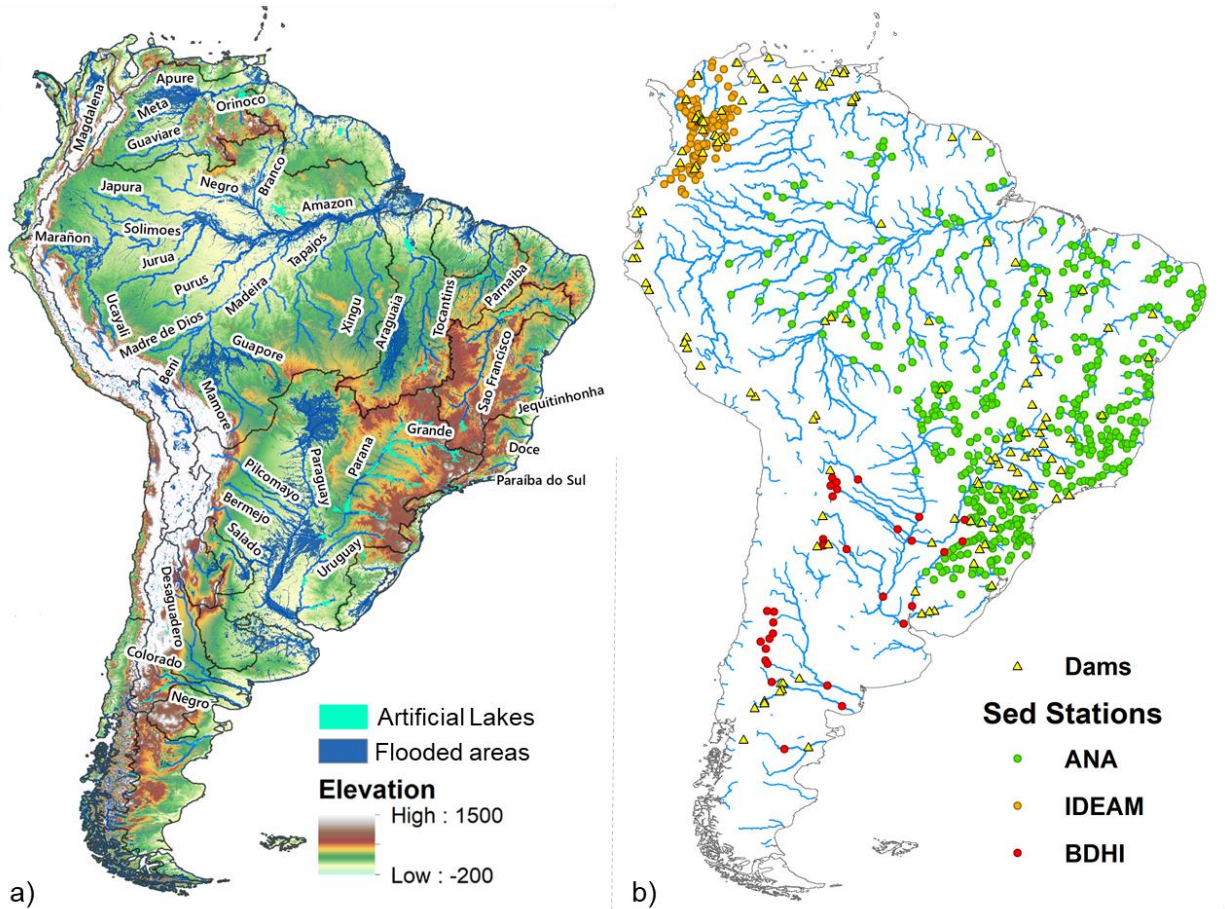

Figure 1: South America showing: a) major hydrological regions according to FAO and *Agência Nacional de Águas do Brasil* (ANA) classifications, relief map based on the Bare-Earth SRTM (O'Loughlin et al., 2016), including main rivers, flooded areas (Fluet-Chouinard et al., 2015) and artificial lakes (Lehner et al., 2011); and b) existent dams from GRanD v1.3 product (>0.1 km³ Lehner et al., 2011 - http://globaldamwatch.org) and from ANA (> 30MW), and sediment stations from ANA, *Base de Datos Hidrológica Integrada da Argentina* (BDHI) and *Instituto de Hidrologia, Meteorologia e Estudos Ambientais da Colômbia* (IDEAM)

The floodplains have an important ecosystem function and storage part of the sediment loads transported in the SA. In the Amazon basin, about 50% of the sediments leaving the Andes are deposited in the floodplains (Guyot et al., 1989), and in the Pilcomayo basin (Figure 1-a), this value is even greater (Latrubesse et al., 2005). Sediment trap also occurs through anthropic factors, such as the presence of impoundments (Figure 1-a), which cause disturbances in river systems, decreasing the sediment load and affecting the geomorphology and the downstream floodplain productivity (Almeida et al., 2015; Grill et al., 2019; Latrubesse et al., 2017, 2005; Restrepo et al., 2006). The highest sediment trap rates (80% - 100%) in SA dams are found in the São Francisco, Tocantins, Orinoco, La Plata and Negro (Argentina) rivers (Syvitski et al. 2005). By using surface samples in the Madeira River, Rivera et al. (2019) estimated a depletion of 30% in the fine suspended sediment concentration after the construction of Jirau and Santo Antonio dams. According to Latrubesse et al. (2017), the existing dams (as well as dams under construction and planned ones) have potential to impact mainly Madeira, Upper Solimões and Tapajós basins.

211 Despite the knowledge provided by previous studies, some things are not yet fully understood:
212 the effect of fluvial hydrodynamics on sediment flows; thoroughly and accurately, the
213 spatiotemporal patterns of denudation rates, concentration (SSC), solid discharge (QSS) and
214 suspended sediment deposition; the driving factors in the relation between SSC/QSS and water
215 discharge; the annual sediment balance of the SA and its main rivers; the potential consequences
216 of climate changes on the patterns of these variables; the impact of dams on rivers and those with
217 the greatest potential to be affected; the relevance of landslides in the sediments transport of each
218 river; and the relative contribution of the anthropic activities, such as mining, to the sediment
219 flows.

220 3 South America Sediment Model

221 To elucidate the South America sediment flows, we used the MGB-SED sediment model
222 (Buarque, 2015; Fagundes et al., 2019, 2020; Föeger, 2019) coupled to hydrologic-
223 hydrodynamic model MGB AS, presented by Siqueira et al. (2018). This modeling configuration
224 was chosen for three main reasons: (i) it is the first fully coupled hydrologic-hydrodynamic
225 model, developed for regional scales, applied for South America's continental domain; (ii) the
226 model has a high temporal resolution (daily outputs) and was validated in most of SA using in-
227 situ and other sources of hydrological data, showing that hydrological variables were well
228 represented; and (iii) the performance of sediment models can be strongly affected by the
229 performance of hydrological models (Cohen et al., 2013; Shen et al., 2012), and the MGB AS
230 has a better performance compared to the global models evaluated by Siqueira et al. (2018).

231 3.1 MGB AS Hydrologic-Hydrodynamic Model

232 The *Modelo Hidrológico de Grandes Bacias* (MGB) was initially developed by Collischonn et
233 al. (2007) and further improved to address different questions (e.g., Fleischmann et al., 2019,
234 2018; Paiva et al., 2011; Pontes et al., 2017; Siqueira et al., 2018). It is a conceptual model, semi-
235 distributed, and has spatial discretization defined by unit catchments (Pontes et al., 2017), each
236 with its own river stretch and floodplain. Precipitation is the main driver of the model (it does not
237 consider snow or ice melting), from which hydrological processes are simulated, such as: canopy
238 interception, soil infiltration, evapotranspiration, and routing of surface, subsurface and
239 groundwater flows. Each unit catchment can have several Hydrological Response Unit (HRU),
240 which is a combination of soil type and soil cover (Kouwen et al., 1993), where water and energy
241 are computed. Surface, subsurface, and groundwater volumes are stored in simple linear
242 reservoirs and further routed to the stream network.

243 In the following, a brief description of the methodology used by Siqueira et al. (2018) is
244 presented. We use the same MGB AS settings and structure, as well as the input data used by the
245 authors. They found agreement between the simulated and observed flows that resulted in a
246 Nash-Sutcliffe efficiency coefficient (NSE) > 0.6 in more than 55% of the analysed stations.

247 Flow routing in the drainage network is performed using the local inertial method (Bates et al.,
248 2010; Pontes et al., 2017). The continuity equation is used to estimate the stored volume, flooded
249 area, and streamflow and floodplain water level. Floodplains are represented as storage areas that
250 compute evaporation in open waters, assuming that water level is constant for the whole unit
251 catchment. Floodplains water infiltration for unsaturated soils are still considered (as described
252 by Fleischmann et al., 2018), specifically for the Pantanal wetlands.

253 MGB AS model also allows using the Muskingum-Cunge (MC) method to routing flows. This
254 method takes a time interval that is subdivided into smaller intervals and also split the total river
255 reach length into sub-reaches to route the flows. The MC method enables the representation of
256 flood wave translation and smoothing, that routes at a velocity c (celerity) higher than average
257 streamflow velocity in a specific time interval and river reach. Among the method advantages
258 are the more straightforward implementation, lower computational efforts, and numeric stability.
259 As for disadvantages, there are the non-representation of backwater effects and lateral exchanges
260 between river and floodplain, which may play an important role in large basins (Getirana and
261 Paiva, 2013).

262 MGB-SA was built using the 15 arcsec HydroSHEDS flow direction map (Lehner et al., 2008)
263 and a minimum drainage area threshold of 1,000km², and basins were discretized into unit-
264 catchments with fixed river lengths equal to 15 km (Siqueira et al., 2018). The Digital Elevation
265 Model (DEM) Bare-Earth SRTM v.1 (O'Loughlin et al., 2016) was used to compute the Height
266 Above Nearest Drainage (HAND), from which the floodplain topography was estimated at a sub-
267 grid level. River hydraulic geometry was set using the global data set of Andreadis et al. (2013),
268 enhanced using information from regional studies (Beighley and Gummadi, 2011; Paiva et al.,
269 2013, 2011; Pontes, 2016).

270 Precipitation data from global Multi-Source Weighted Ensemble Precipitation – MSWEP v1.1
271 (Beck et al., 2017) were used. The climatic variables used to estimate evapotranspiration were
272 temperature, atmospheric pressure, income shortwave solar radiation, relative humidity, and
273 wind speed obtained from Climate Research Unit (CRU) Global Climate v.2 (New et al., 2002).
274 They are long-term monthly averages (1961-1990) and have 10' spatial resolution. South
275 America HRUs map from Fan et al. (2015) was used to represent soil type (shallow and deep)
276 and soil cover.

277 For more details about approaches, equations, and data, a full description can be found in
278 Siqueira et al. (2018).

3.2 MGB-SED sediment model

280 The *Modelo de Sedimentos de Grandes Bacias* (MGB-SED) was introduced by Buarque (2015)
281 and improved in other studies (e.g., Fagundes et al., 2020; Fagundes et al., 2019; Föeger, 2019).
282 The MGB-SED has three modules (basin, river and floodplain) and enables the simulation of rill
283 and interrill erosion processes in hillsides, bed river erosion and deposition, sediment transport
284 through the river network, and deposition of suspended sediment in the floodplains.

285 The sediment volumes from hillsides to river reaches in each unit catchment is the primary
286 information estimated by the model using the Modified Universal Soil Loss Equation (MUSLE)
287 (MUSLE, Williams, 1975) :

$$Sed = \alpha.(Q_{sur} * q_{peak} * A)^{\beta}.K.C.P.LS_{2D} \qquad (1)$$

289 where Sed[t/day] is the sediment yield, Q_{sur}[mm/day] is the specific runoff volume, q_{peak}[m³/s]
290 is the peak runoff rate, A[ha] is the unit catchment area, K[0.013.t.m².h./m³.t.cm] is the soil
291 erodibility factor, C[-] is the cover and management practices factor, P[-] is the conservation
292 practices factor, LS_{2D}[-] is a bidimensional topographic factor; and α and β are the fit
293 coefficients of the equation (which are calibrated afterward), whose values originally estimated
294 by Williams (1975) were 11.8 and 0.56, respectively.

295   Q_{sur} and q_{peak} values are estimated by the coupled hydrologic model (MGB AS in this study). P
296   factor is estimated from the knowledge of soil management and conservation practices but has
297   been adopted as 1 in most large scale applications (e.g., Benavidez et al. 2018; Borrelli et al.
298   2017; Naipal et al. 2015; Phinzi and Ngetar 2019). C factor is usually calculated from field
299   experiments but has been usually adopted from literature for each soil cover, as presented by
300   Benavidez et al. (2018) and Phinzi and Ngetar (2019). MGB-SED model computes K factor
301   from Williams (1995) equation, in which considers the soil texture (sand, silt and clay
302   percentages) and amount of soil organic carbon. LS_{2D} factor is estimated by the model using a
303   DEM (Buarque, 2015) and more details about the LS_{2D} estimates can be verified in the
304   supplementary material S1.

305   The approach used by MGB-SED to estimate sediment yield using MUSLE equation is the same
306   used in other models, as SWAT (Arnold et al., 1998), CREAMS (Knisel, 1980), PERFECT
307   (Littleboy et al., 1992) and SWIM (Krysanova et al., 1998). We are aware of the known
308   limitations of this approach, as it does not explicitly consider all erosive processes such as those
309   related to mass movements. Some authors like Tan et al. (2018) have already improved the
310   estimates of a sediment model by including the representation of shallow landslides. However, as
311   an initial approach and because it has already presented itself sufficiently in other large-scale
312   modeling applications (e.g., Buarque, 2015), we use it, and we are aware of the limitations it
313   imposes on the analysis of the results.

314   After computing sediment yield by MUSLE, the estimated volume is divided into three classes
315   of particle sizes (silt, clay and sand), according to the percentage of these classes in the soil.
316   Three linear reservoirs (one for each class) are used for the sediment routing from the hillsides to
317   the drainage network. Each soil particle size is then routed from upstream to downstream using
318   the following approaches: (i) for the fine loads (silt and clay), the unidimensional transport
319   equation without the diffusion term is used, and the sediments are transported in suspension,
320   without deposition in the channel; (ii) for sand, considered as bed load, the Exner sediment
321   continuity equation is used together with the Yang transport capacity equation (Yang, 1973) to
322   quantify the transport in the channel, the erosion or deposition in the bed. It is worth mentioning
323   that in this study only the transport of suspended sediment load (silt+clay) is evaluated.

324   In the floodplains, a zero longitudinal velocity is assumed, and only river-floodplain exchanges
325   are possible. The perfect mixing in the floodplains is also assumed, which implies constant
326   concentrations of silt and clay in the vertical profile. Floodplains work as storage areas, where
327   fine particles can be deposited but cannot be resuspended. Sediment deposition in the floodplains
328   is estimated considering the fall velocity proposed by Wu and Wang (2006). Sediments that do
329   not deposit flow back to the main channel.

330   More details about model equations can be found in the supplementary material S1. A summary
331   of the coupling between the two models that resulted in the MGB-SED AS, main input data,
332   processes, and outputs are shown in Figure 2.

Figure 2: MGB-SED AS scheme. The blue (brown) part is related to the hydrological (sediment) model, its structure, main input data, processes, and main outputs.

3.3 Simulation Input Datasets

MGB-SED model requires topographic, soil type, texture and cover, and surface runoff to estimate daily sediments using the MUSLE equation. To compute K factor (Figure 3-a), we use percentages of silt, clay, sand and organic carbon for each soil type from the Food and Agriculture Organization (FAO) of the United Nations (FAO/UNESCO, 1974). LS_{2D} factor (Figure 3-b) was estimated using Bare-Earth SRTM v.1 DEM (O'Loughlin et al., 2016). We use each land cover identified in URH South America map (Fan et al., 2015) to compute C factor (Figure 3-c) based on previous studies (Benavidez et al., 2018; Buarque, 2015; Fagundes et al., 2019). It is worth mentioning that C values for the forest were not the same throughout SA, due to the heterogeneity of forest coverings (see Figure S1 - Supporting Information). P factor was adopted equal to 1, since in that scale there is no detailed information about soil conservation practices.
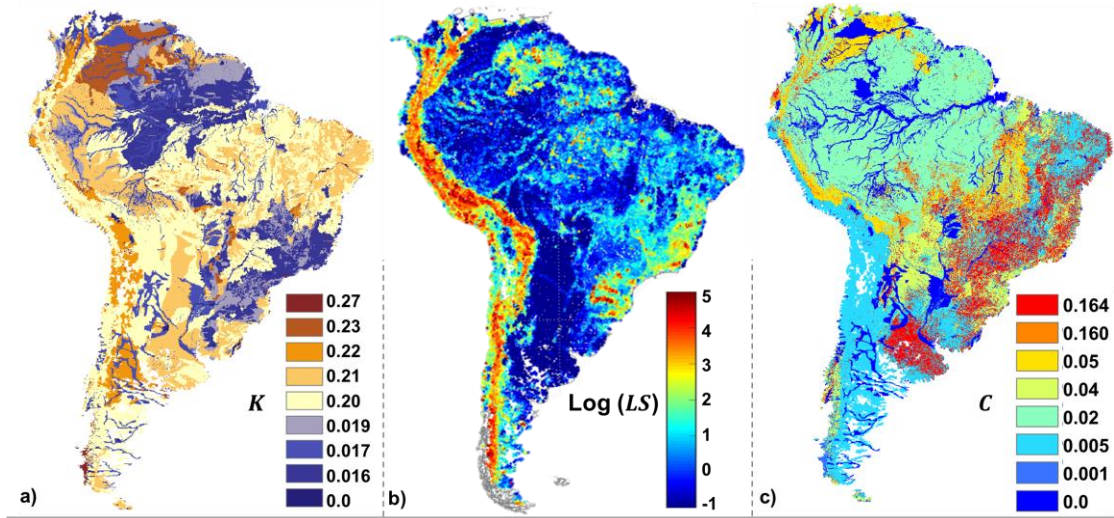

348

Figure 3: MUSLE parameters adopted for South America: a) K [0.013.t.m².h./m³.t.cm] factor; b) Log (LS_{2D}) [-] factor; and c) C [-] factor.

As mentioned before, the daily runoff was estimated by MGB AS and it was also used to compute q_{peak}. From this data and other simulated hydrological variables (e.g., river discharge and water level, and floodplains stored volumes), it was possible to compute soil loss and sediment transport using the same spatial discretization of MGB AS. We have chosen to change the values of the adjustable parameters α and β, as it has been done in several works (see the review presented by Sadeghi et al. (2014)), including previous applications with the MGB-SED model (e.g., Fagundes et al., 2019).

3.4 Experimental Design

3.4.1 Model Calibration and Evaluation

The base period for the analysis and performed simulations using the MGB-SED AS model was 1990-2009, in which the first two years were used to warm up the model. Initially, we performed a mass balance to check if the model was generating numerical errors, adding or removing mass in the simulation.

In order to know the natural (without impoundments) simulated sediment loads transported by the rivers, it was necessary to evaluate the performance of the MGB-SED AS model. For that, we used suspended sediment discharge (QSS) of the 595 in-situ stations (Figure 1-b) in Brazil - ANA (450), Colombia - IDEAM (109) and Argentina – BDHI (36). Suspended sediment is measured using cross-sectional mean sediment mass concentration, using the ISO 4363 (2002) protocol as reference. There are differences depending on river width and discharge. The main difference is found for IDEAM information, in which daily surface samples are taken and correlated against cross-sectional mean sediment mass concentration (IDEAM, 2007). ANA, BDHI, and IDEAM provide information of suspended sediment quarterly, monthly, and daily, respectively. Moreover, as samples are often not collected during flood events (in cases of ANA and BDHI), time series may be biased due to the predominance of data from the dry period. To address this continental sediment modeling we assume that uncertainties related to different sampling methods are not enough to prevent a comparison against modeling results.

377 To increase confidence and consistency, we used only databases for which samples are taken
378 from the whole cross-section, or data are derived from the latter. Both observed data and
379 simulations do not consider the organic solids. Free sediment data from other countries were not
380 found. To better explore the data, stations having at least 4 measurements in the period of 1992-
381 2009 and drainage area above 1,000 km² were selected.

382 In the calibration (2002-2009), 77 stations were used, with drainage areas ranging from 3,045 to
383 4,700,503 km². The calibration stations were selected as follows: i) we always choose stations
384 with the largest drainage area for each monitored sub-basin; ii) in case stations were located
385 downstream of one (or more) reservoir (Figure 1), the one upstream with the largest drainage
386 area would be used; iii) when there was just one station in a sub-basin, it was used to calibrate
387 the model.

388 The calibration was performed in two stages: an automatic calibration followed by a manual
389 calibration. Automatic calibration was performed using the MOCOM-UA optimization algorithm
390 (Yapo et al., 1998) following the recommendations proposed by Fagundes et al., (2019). The
391 algorithm MOCOM-UA requires setting some parameters and initial conditions. We used a
392 population of 100 individuals; three objective functions - Nash-Sutcliffe efficiency (NSE, Nash-
393 Sutcliffe, 1970) efficiency coefficient, $BIAS$, and error in the slope of the duration curve between
394 10% and 50% ($DCPerm$, Kollat et al., 2012); maximum of 500 iterations; and three calibration
395 parameters: $\alpha \ and \ \beta$ (Equation 1) and Ɣ (Equation 2). These parameters were adjusted to each
396 model sub-basin.

397
$$ t = Ɣ.TKS \tag{2} $$

398 TKS (s) is the parameter which indicates the delay time of the surface linear reservoir output
399 (Collischonn et al., 2007); t (s) indicates the travel time of the sediments to the drainage network
400 (see Text S1 in the support information S1); Ɣ [-] is the adjustment factor between the two
401 aforementioned parameters. It means that surface runoff and sediment load transport can have
402 different travel times between the hillsides and channels, and Ɣ can increase or decrease this
403 difference. This approach is used to better represent the sediment processes, and overcome some
404 limitations due to the use a large-scale sediment model. The range of values used for the
405 calibration parameters α, β and Ɣ was, respectively, 0.01-25.0, 0.1-0.5 and 0.1-5.0.

406 For the basins where we have not data, a simple transfer of parameters from the calibrated sub-
407 basins was made. The transfer process was based on the physical and climatic characteristics of
408 the region.

409 For the validation (1992-2009), the same criteria of the calibration stage were used, resulting in
410 the selection of 56 sediment stations. A global evaluation of the model performance was also
411 carried out using the 595 stations. It was a conservative decision, which includes the model
412 evaluation for the 1992-2009 period with the stations used (77) and those not used (518) in the
413 calibration process. In addition to the metrics already mentioned, the model performance was
414 evaluated using Pearson's correlation coefficient (r), Kling-Gupta (KGE) efficiency coefficient
415 and relative value of Root Mean Square Error ($RMSE$).

416 MGB-SED AS results were compared to estimates from several regional studies (see Table S1 -
417 Supporting Information). The comparison was performed using data of long-term average annual
418 QSS from 80 sites exceeding a drainage area of 5,000 km² (see Table S1 and Figure S2,

419 Supporting Information). The agreement between QSS simulated and those of regional studies
420 was evaluated from the relative difference between the annual values (Equation 3).

421 $$Diff(\%) = 100x \frac{QSS\ MGB\text{-}SED\ AS - QSS\ reg.studies}{QSS\ reg.studies} \qquad (3)$$

422 Positive (negative) $Diff$ values mean that MGB-SED AS model calculated values higher
423 (lower) than those from regional studies used in the comparison.

424 QSS simulated was also compared to the outputs of the global sediment model WBMsed (Cohen
425 et al., 2014). This model was selected because it is the only one with data freely available for
426 society. It is a grid model with 6 arc-min (~11km) spatial resolution and uses the Muskingum-
427 Cunge method to route daily water streamflows (Wisser et al., 2010). To estimate the QSS,
428 firstly, the model computes the long-term average values using global empirical equation
429 BQART (Syvitski and Milliman, 2007) and then it uses the Psi model (Morehead et al., 2003) to
430 compute daily data. In the version presented by Cohen et al. (2014) the floodplains were
431 represented as temporary (final) storage areas for water (sediment). It means that the flows reach
432 the floodplains when the bankfull discharge is exceeded, and water can return to the river when
433 discharge is below bankfull.

434 The $Diff(\%)$ was also used for the comparisons between MGB-SED AS and WBMsed outputs
435 in 51 sites (see Table S2 and Figure S2, Supporting Information). The WBMsed grid cells
436 identification was performed manually, and the selected sites are the same as the in-situ stations
437 used for the comparisons against regional studies, which enable contrasts between scales and
438 studies. Long-term average QSS were computed with both models in the period 1993-2009. The
439 WBMsed outputs can be obtained at https://sdml.ua.edu/datasets-2/datasets/.

440   3.4.2 Analysis of Sediment Flows in South America

441 A study of QSS patterns was conducted using time series, from the calibrated model. QSS were
442 simulated using the inertial and Muskingum-Cunge routing methods to assess the impact of
443 fluvial hydrodynamics and floodplains on sediment transport and deposition. We also evaluate
444 the effect of calibration and hydrodynamic routing on sediment delivery to the Oceans. For this
445 purpose, we compared the estimated loads from a simulation considering hydrodynamic routing
446 without calibration (i.e., setting the values 11.8 and 0.56 for parameters α and β, respectively)
447 versus simulations using the inertial and Muskingum-Cunge methods to estimated loads
448 considering the calibrated model.

449 To understand the spatial dynamics of the sediment flows in the SA, long-term averages of SSC,
450 denudation rate, deposition of suspended sediment in the floodplains, and water discharge were
451 calculated. We identified the major floodplains where the highest deposition rates occur, but the
452 results were only presented for those basins where the model was calibrated, i.e., where there
453 was no transfer of parameters, as in the case of the Orinoco River basin. We also computed the
454 annual sediment balance at the outlets of the large rivers and for the whole SA.

4 Results and Discussions

4.1 Model Validation

4.1.1 Simulated data vs. in-situ observations

The mass balance analysis (Table S3, Supporting Information) showed that the MGB-SED AS model remained stable throughout the simulation. Numerical errors were of the 10^{-2}% order, mostly coming from variables truncation in the operations.

The simulated QSS was compared against observed daily values, and the performance of the model was evaluated in Figure 4 in terms of r, $BIAS$ and NSE. Other metrics are shown in Figure S3 of the Supporting Information. The better performance is found in the Amazon, Tocantins, São Francisco and Doce basins.

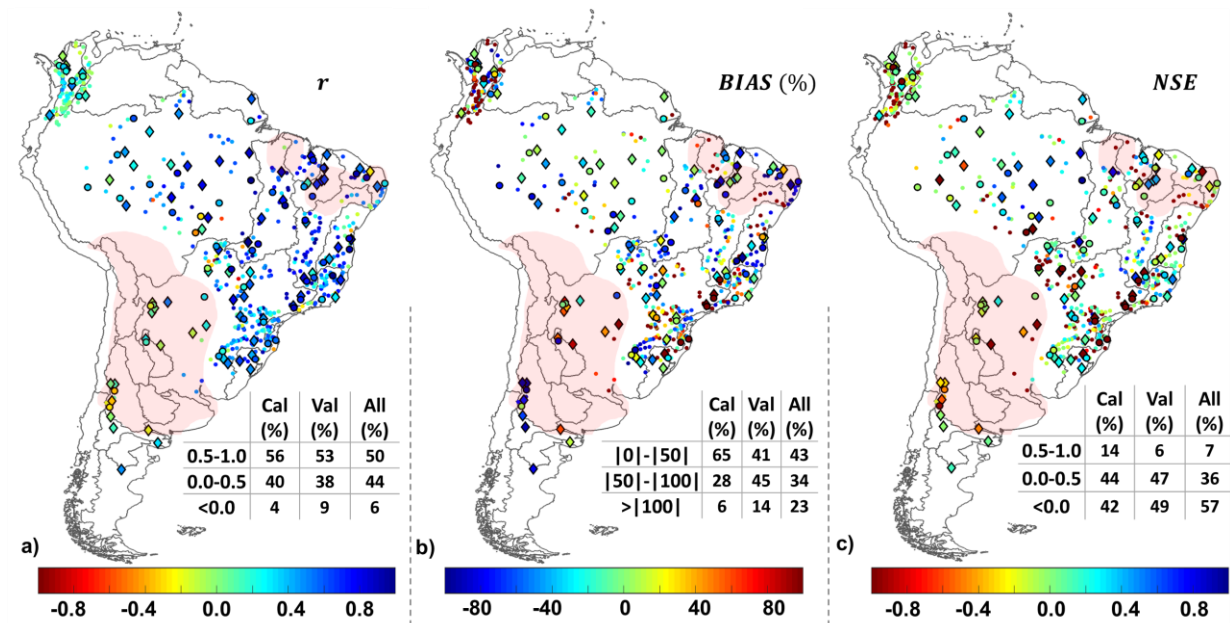

Figure 4: MGB-SED AS performance over South America in terms of suspended sediment discharge: a) correlation (r); b) $BIAS$ (%); and c) Nash-Sutcliffe efficiency (NSE). Diamonds and bigger dots refer to stations used in calibrating (Cal) and validating (Val) steps, respectively. Small dots refer to other station used to evaluate the model. Tables summarize the percentage of sediment stations in each performance class and corresponding step. Marked regions represent those with poor hydrological-hydrodynamic performance (see Siqueira et al., 2018).

Figure 4-a indicated agreement between model estimates and observed data in terms of correlation, in which 56% and 53% of the stations had values higher than 0.5 in the calibration (Cal) and validation (Val) steps, respectively. In terms of $BIAS$, 94% (Cal) and 86% (Val) of the stations had values between -100% and 100% (Figure 4-b). For NSE, 58% and 53% of the stations had positive values (Figure 4-c). Some underestimates (negative $BIAS$) can be due to high rates of sands in suspension, as pointed by Santini et al. (2019) for the upper areas of Amazon basin. According to the authors, these rates tend to decrease from upstream to downstream. Detailed views of regions having high density of stations are shown in Figures S4, S5 and S6 (Supporting Information).

In the evaluation using all stations (All), Figure 4 shows that MGB-SED AS model had a lower performance in comparison to calibration. We observed a better model performance to

simulate QSS for stations used in the calibration, and worse model performance (r, *NSE*<0.0 and *BIAS*>|100) was noticed especially in three situations. The first one is related to the regions where the hydrological model performed poorly (Figure 4), characterized by arid or semi-arid climate; regions where snow melting plays an important role for the runoff generation; and regions influenced by orography (Siqueira et al., 2018). The second one is represented by rivers influenced by the presence of dams, which affect the sediment transport, such as the São Francisco, Jequitinhonha, Tocantins, Paraná, Salado, Madeira, Parnaíba and Doce rivers (See Figure 1 and Figure 4). The third one is for the stations having small drainage areas. For the latter situation, Figure 5 presents a detailed description of the modeling results that relate the drainage area of each station to the *NSE* and *BIAS* values. It is noted that for areas larger than 100,000km², the *BIAS* range is reduced (values between -67% and 200%), remaining mostly between -50 and 50% (Figure 5-b). For the NSE, most values are over -0.5 (Figure 5-a). Basins draining small Andean areas are very susceptible to landslides, delivering a large amount of sediments to the rivers (Restrepo et al., 2006; Martín-Vide et al., 2014). As mentioned before, MGB-SED AS does not explicitly represent landslide processes, showing low performance in these areas (e.g. headwaters of Magdalena, Bermejo and Pilcomayo rivers).

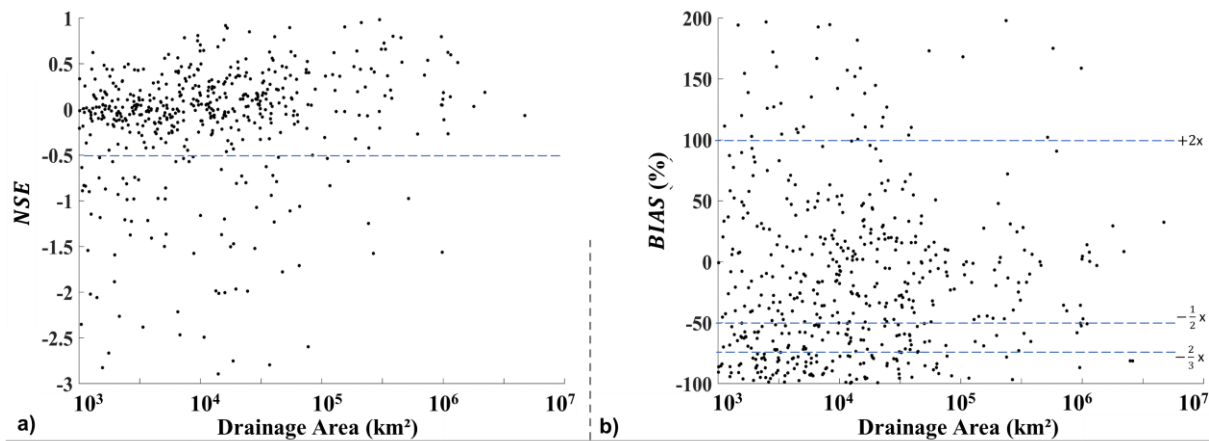

Figure 5: *NSE* and *BIAS* (%) between observed and simulated QSS compared against the drainage area. Dashed blue lines in b) represent how much MGB-SED AS model over or underestimate QSS values.

Many stations that have small drainage areas are found in Colombia, for example. The results of Figure 4 in this region do not show a specific pattern, and the *NSE* and *BIAS* values are sometimes negative, sometimes positive (see Figures S5, S6 and S7, Supporting Information). These basins also have high slope values and are characterized by the occurrence of strong storms (Restrepo et al., 2006). Also, sediment data from IDEAM are estimated by using a relationship between surface measurements and cross section measurements. This can be a source of uncertainties that must be taken into account when interpreting the results. The resolution of the models input data and the computational resources generally available make it difficult to represent these features in continental-scale models.

In Table S5 of the Supporting Information, we present an analysis of the model performance for several stations and the period when the model was calibrated (2002-2009) and the non-calibrated (1992-2001). The analysis shows that temporal extrapolation performed better than spatial extrapolation. The temporal extrapolation refers to the model evaluation for calibrated stations in another period. Spatial extrapolation refers to the model evaluation in the same period as the calibration, but for stations not used in that process.

516   4.1.2 Simulated data vs. other studies

517   The comparison between simulated annual QSS and estimated annual QSS by regional
518 studies showed an R²=0.87 (Figure 6-a). 61% of comparisons revealed that the MGB-SED AS
519 estimates range between half and twice the values found in regional studies.

520   Figure 6-a also shows a trend for MGB-SED AS QSS to be lower than the regional
521 studies QSS. Figure 6-b presents a comparison of $BIAS$ (MGB-SED SA and in-situ measured
522 data) versus $Diff$ (MGB-SED SA and regional studies). The results indicate that the $BIAS$ and
523 $Diff$ median were, respectively, -3% and -23%.

524   To understand the differences presented in the previous paragraph, we highlight that: i)
525 the medians of $BIAS$ and NSE were, respectively, -3% and 0.11 for the 49 analyzed stations; ii)
526 in the Altamira station, for example, the daily $BIAS$ and NSE were, respectively, 0% and 0.78,
527 but in comparison with Filizola and Guyot (2009)study, the MGB-SED AS has estimated for this
528 station QSS values 55% lower; iii) the regional studies (Table S1, Supporting Information)
529 provided estimates using regression methods between QSS and water discharges. From the three
530 points presented, we realize that MGB-SED AS had better agreement with in-situ data (for the
531 most comparisons) than with estimated data from regional studies. Besides, the regression
532 methods used in the aforementioned studies are simplified, and they consider some assumptions
533 that may increase their estimates, such as: the use of few in-situ measured data, in which the
534 majority belonging to the low-concentration period, to represent the temporal dynamics of
535 sediments; Q enough to explain QSS; the increase of QSS is always increasing with Q. However,
536 because of hysteresis effects, it is known that these premises often do not occur in nature,
537 especially for large rivers, which is clearly demonstrated for the Amazon in studies performed by
538 Bourgoin et al. (2007), Filizola et al. (2011) e Fassoni-Andrade and Paiva (2019). A broader
539 discussion on this topic is presented in the next section.

540   The worst performance of MGB-SED AS was at Javari station (ID=45, Figure S2 and
541 Table S1 - Supporting Information), where $BIAS$ and $Diff$ were, respectively, -95% and 92%.
542 Javari station has a drainage area closer to 1×10^4 km² and the model calibration in the same sub-
543 basin was performed by having focus on Solimões station (ID=47, Figure S2 - Supporting
544 Information), which has a drainage area closer to 1×10^6 km². Situations like this show the
545 difficulty to achieve a model with high performance to estimate daily QSS for all the continental
546 domain and why the model has a better performance for stations with larger drainage areas
547 (Figure 5).

Figure 6: Performance of the MGB-SED AS model against in-situ observations, the results of regional and global studies. a) comparison between MGB-SED AS annual suspended sediment discharge (QSS) and QSS from regional studies; light gray dots refer to when the MGB-SED AS estimated more than double or less than half the regional studies values. b) comparison between daily simulated (MGB-SED AS) and observed (in-situ) QSS ($BIAS$) against annual simulated QSS (MGB-SED AS), and estimated from regional studies ($Diff$). c) comparison between daily simulated (MGB-SED AS) and observed (in-situ) QSS against annual simulated QSS from MGB-SED AS, and from the WBMsed global model (Cohen et al., 2014), using $BIAS$ and $Diff$, respectively. In figure b (c): a point exactly at the origin (x,y)=(0,0) means that both the results simulated by MGB-SED AS and those from regional studies (global model) have strong agreement with the in-situ observations; the point (x,y)=(-100,-100) means that the MGB-SED AS model had a poor performance compared to the observed data and a worse performance than the results of the regional studies (global model); the point (x,y)=(-100,0) means that the MGB-SED AS model performed better, if compared to the observed data, than the values estimated by regional studies (global model).

561

562   Figure 6-c presents a comparison between the results of MGB-SED AS and those of the
563   WBMsed global model (Cohen et al., 2014). The median $Diff$ between the MGB-SED AS and
564   the WBMsed model was -74%. It shows that the estimated values by MGB-SED SA are
565   considerably lower than those predicted by WBMsed. In this case, although the WBMsed model
566   does not consider only Q to estimate QSS, it is based on a global empirical equation, which may
567   have limitations given the different variables around the globe.

568   After an analysis of Figure S2 and Table S2 (Supporting Information), no spatial pattern
569   of the $Diff$ metric was found. WBMsed showed a tendency to overestimate both MGB-SED AS
570   and in-situ measurements. This can be related to several aspects, like: i) differences in
571   precipitation grids used by the models and their associated resolution; ii) differences in
572   computing slopes, which can greatly affect the erosion rates (Garcia-Ruíz et al. 2015); iii)
573   Muskingum-Cunge method to route the flow, which is not suitable to represent backwater and
574   floodplain effects for several South America regions (e.g. Angarita et al., 2018; Bravo et al.,
575   2012; Paiva et al., 2013, 2011; Pontes et al., 2017; Siqueira et al., 2018; Zhao et al., 2017) ; and
576   iv) the QSS estimated by the WBMsed model was neither calibrated nor validated by Cohen et
577   al. (2014) in SA. However, it is worth mentioning that the complexity of the WBMsed makes it
578   difficult to accurately compare the factors that impact sediment estimates.

579

580   The tables used to generate Figure 6 graphics can be found on the Supporting Information
581   (Table S1 and Table S2).

582   4.2 Analysis of Sediment Flows in South America

583   4.2.1 Time Series

584   Figure 7 presents the comparison between daily simulated and in-situ QSS data for
585   several large South American rivers. The presented statistics were calculated considering only
586   the values of observation dates. Apavi station, on the Magdalena river (Figure 7-1), offers a lot
587   of observed data, and, in general, there was an agreement between the simulated and observed
588   data ($BIAS$=-6% and NSE=0.29). In the Amazon basin, suspended sediments were well
589   represented for several stations, which can be seen in the Fazenda Vista Alegre (Figure 7-3) and
590   Altamira (Figure 7-3) stations. The latter had $BIAS$=0% and NSE=0.78. Óbidos station (Figure
591   7-2) show a $BIAS$ of 30%, while upstream station showed values closer to 0% (Figure 4-b).
592   According to Filizola and Guyot, (2009), Óbidos station has a particular protocol, where
593   sampling is taken only in the surface zone, underestimating the real concentration (Bouchez et
594   al.,2011). This explain why Óbidos station has a $BIAS$ value in disagreement with their upstream
595   stations.   It is pointed out that the variability of the QSS estimated by the sediment model is
596   strongly influenced by the variability of hydrological variables calculated by MGB AS (see
597   Equation 1).

598   The impact of fluvial hydrodynamics on sediment transport can be observed at Fazenda
599   Vista Alegre, Óbidos, Puerto Pilcomayo (Figure 7-8) and Brazo Largo (Figure 7-10) stations,
600   where backwater effects and floodplain storage reduce the sediment transport by 16%, 13%,
601   55%, and 30%, respectively. In other places like Altamira (Figure 7-4) and Paraná (Figure 7-9)
602   stations, sediment transport was reduced by 6%. These are regions where rivers generally have

603 higher slopes and the effect of floodplains is less expressive. 36% of simulated river reaches
604 showed sediment storage in floodplains greater than 1 t/year. More information about the
605 importance of floodplains are presented in the next sections.

606

607 **Figure 7:** Comparison between observed (QSSobs - black asterisks) and simulated suspended sediment discharge
608 (QSS) for some large rivers of South America. Model performance is presented in terms of correlation (*r*),

manuscript submitted to *Water Resources Research*

609
610
611
612

613   In the Propriá station, the *BIAS* was 665%, and in-situ QSS values were always very low
614 (Figure 7-5). In this case, as for other stations like Paraná (*BIAS* 2337%, Figure 7-9), these low
615 observed values are associated with sediment trap in large dams located upstream. Highlighting
616 this phenomenon is important because, in these cases, the observed temporal dynamics are
617 inconsistent with the simulated natural sediment discharge in the rivers.

618   The Puerto Pilcomayo station (Figure 7-8), in the Paraguay River, also showed low
619 performance, which can be related to the difficulty of the MGB AS model to represent the strong
620 deposition that occur in the Pilcomayo River (upstream the Pilcomayo, *BIAS* has negative
621 value). Due it and large impoundments in the Paraná River, MGB-SED AS overestimate the
622 observed values of QSS in the outlet of the La Plata River (Figure 7-10)

623   In many places, the model estimates and in-situ observations did not match, which may
624 have been caused by the non-representation of reservoirs in the modeling process. In the São
625 Francisco River, sediment trapped by reservoirs may approach 70% (Creech et al., 2015).
626 Syvitski et al. (2005), considering impoundments, estimated that sediment flows to the oceans in
627 SA were reduced by about 13%/ year. The expectation of the construction of new dams in the SA
628 and their impacts on water and sediment flows, mainly in the Amazon Basin (Latrubesse et al.,
629 2017), have grown. Besides, studies like Dunn et al.(2018) and Dunn et al. (2019) have shown
630 the importance of quantifying sediment flows in the present and future scenarios because large
631 and important rivers around the world have stopped supplying their deltas.

632   Figures S8, S9 and S10 show the number of QSS observed data for each sediment station.

633   4.2.2 Spatial Analysis

634   Figure 8-a presents the long-term average annual QSS (t/year). From the simulated
635 results, the Amazon River is the one with the highest QSS (4.36×10^8 t/year), followed by the
636 Orinoco (1.37×10^8 t/year),La Plata (1.11×10^8 t/year) and Magdalena (3.26×10^7 t/year) rivers.
637 The Magdalena carries a load for times greater than those carried by the São Francisco (7.46×10^6
638 t/year) and Tocantins (7.44×10^6 t/year) rivers, which have twice their drainage area. The average
639 flows of the São Francisco and Tocantins rivers are 56% lower and 88% higher, respectively,
640 than the Magdalena river. The Doce River transports a suspended load of 5.04×10^6 t/year, which
641 is equivalent to 70% of the load carried by the Tocantins River, although the Doce River has a
642 drainage area (flow) ten (fourteen) times smaller.

643   Andean rivers flowing to Pacific Ocean also exhibit high rates of sediment transport
644 (QSS~10^7 t/year), except for dry regions like in the northern Chile. These Andean rivers show
645 QSS values in the same order of São Francisco and Tocantins rivers (Figure 8-a), which places
646 them among the main sediment transporters of the SA, although they drain a considerably
647 smaller area.

648   The simulated QSS for the most downstream stations of each basin agreed with the
649 observed values (*BIAS* values, Figure 4). Figure 8-a represents a natural potential transport
650 situation in the rivers, since a sediment trapping in dams was not considered in the sediment
651 modeling. Rivers such as the São Francisco and Paraná, for example, currently have field clearer

652 waters downstream from the dams in comparison to what is suggested by the sediment
653 simulation.

**Figure 8:** Average Annual a) suspended sediment discharge (QSS) over South America; b) denudation rate (silt+clay+sand); and c) $\alpha(Q. q_{peak}. A)\beta$. Colorbar values are in the logarithmic scale. Numbers in c) refer to stations showed in Figure 7.

658 Figure 8-b shows spatial patterns of denudation rates (soil loss in mm/year; sediment
659 density equal to 2.65 t/m³ was used for the unit conversion, see Morris and Fan, 1998). The SA
660 average value is 4.6 mm/year. With 16.62 mm/year, the Magdalena basin presented the highest
661 mean denudation rate. The Amazon basin had the second-highest denudation rate of 6.8
662 mm/year. In the Solimões, Madeira and Juruá river basins, denudation rate was 16.15, 9.89 and
663 5.03 mm/year, respectively. For the Negro, Tapajós and Xingu watersheds, these values were
664 0.41, 0.40 and 0.28, respectively.

665 The high denudation rates calculated for the Magdalena and Amazon river basins are
666 mainly associated with the high slopes and strong storm events in the Andean region (see Guyot
667 et al., 1996; Restrepo et al., 2006). The Restrepo et al. (2006) analysis, between 1986 and 1996
668 using more than 30 stations, indicated an increasing trend of erosion in the Magdalena basin.
669 Among the causes for this increase are catchments with small drainage areas having high relief
670 and narrow alluvial plains, heavy precipitations, and changes in land use and land cover.
671 Furthermore, compared to the Amazon, the Magdalena basin is more influenced by the Andes
672 and has fewer flat regions (Figure 1). Paraguay (7.48 mm/year) and Orinoco (5.71 mm/year) also
673 have high denudation rate values.

674 The Paraíba do Sul, Doce and the Paraná river basins also stand out with high denudation
675 rates: 5.34 mm/year, 2.12 mm/year and 3.52 mm/year, respectively. These basins have a strongly
676 undulating and hilly relief, soils covered mainly by agriculture and degraded pastures, and a very
677 seasonal rainfall pattern, with heavy rainfall for the November-January period. Despite the
678 Parnaíba and São Francisco river basins having a hilly relief, they are in a semi-arid region, for
679 which lower denudation rates are estimated (0.28 mm/year and 0.85 mm/year, respectively).

680   The relations between denudation rate, slope (represented by the *LS* factor), and
681 precipitation (represented by the Aridity index) are presented in Figure 9. Red dots in Figure 9-a
682 and Figure 9-b, correspond to rivers for which the LS factor and Aridity Index are above the
683 percentile 95%, respectively, which indicate steeper (Figure 9-a), and extremely dry (Figure 9-b)
684 areas. This figure shows, in agreement with Figure 3 and Figure 8, that high denudation rates
685 can occur for high and low slopes, and are found mainly in humid areas (Aridity Index <100,
686 Figure 9-a), while arid regions always have very low denudation rates (Figure 9-b). Figure 9
687 shows that a pattern between the denudation rate, *LS* factor and aridity index does not exist. We
688 expected this, since the model considers several processes based on what occurs in nature, and
689 not only the water discharge, to estimate erosion and sediment transport. García-Ruiz et al.
690 (2015) identified, from several studies around the world, that almost all erosion rates can occur
691 for any climate condition. The authors also pointed out that a significant effect of the increase in
692 erosion rates occurs as precipitation and slope rise. This increase tends to reach, on average, a
693 limit when the slope and precipitation reach ±0.2m/m and ±1,400mm/year, respectively.

694

Figure 9: Denudation rate versus: a) Aridity Index (red dots represent *LS* values above the percentile 95%); b) *LS*
factor (red dots represent Aridity Index values above the percentile 95%).

697   The MUSLE factor related to the ability to remove soil particles is the $\alpha(Q.q_{peak}.A)\beta$.
698 In regions such as Brazilian northeast, Chaco, Atacama Desert, and others in the south of the
699 continent (Desaguadero, Colorado and Negro river basins), the values of this factor are
700 comparatively low concerning the rest of the SA. High values are found in the Pantanal, Purus
701 River basin, part of the Juruá River basin, and in the lower La Plata river basin (Figure 8-c). It is
702 noticeable that some spatial patterns presented in Figure 8-b are directly related to the standards
703 presented in Figure 8-c, showing the influence of the $\alpha(Q.q_{peak}.A)\beta$ factor in the denudation
704 rate.

705   In the Pantanal, Juruá River and Purus River, even the $\alpha(Q.q_{peak}.A)\beta$ factor values
706 being higher, the simulated QSS tended to underestimate the observed values (Figure 4). Thus,
707 we believe that these highlighted values may be related to the calibration parameters of the
708 hydrological model and the spatial discretization performed by Siqueira et al. (2018), which was
709 more focused on hydrological processes than sediment processes. Also, no pattern was observed
710 in the maps of the input parameters (Figure 3) that could explain the observed pattern for the
711 Purus and Juruá river basins in Figure 8-b. The high values in the La Plata river basin may be
712 associated with large wetlands, which produces high runoff but low sediment yield.

713   4.2.3 Multiple relationships: water discharge, sediment concentration and deposition

714   4.2.3.1 Overview

715   Figure 10 shows SA rivers with the highest Q and SSC values according to the modeling
716 results. The figure illustrates that largest SSC values in the Amazon basin are located in the
717 upper Madeira River and other rivers having the headwaters in Andean regions, as already
718 known by previous studies (Amsler and Drago, 2009; Cohen et al., 2014; Latrubesse et al.,
719 2005). The pattern found in the river reaches with higher and lower concentrations in the central
720 Amazon matches well with the results found by Fassoni-Andrade and Paiva (2019) using remote
721 sensing. The greatest differences are found downstream of the confluence between the Amazon
722 and Tapajós rivers, where the SSC (Figure 10) keeps decreasing, while Fassoni-Andrade and
723 Paiva (2019) observed an increase downstream of the confluence with the Xingú River. The
724 authors concluded that this difference could be associated with sediment resuspension caused by
725 variations at the Amazon estuary, which are not represented in the MGB-SED AS model.

726   The Magdalena, Bermejo, Pilcomayo, and some rivers in the south of SA showed high
727 concentrations. The Amazonian rivers without headwaters in the Andes have low SSC, such as
728 the Negro, Tapajós and Xingu rivers (Figure 10), having high water discharge values (>9,700
729 m³/s in average, see Filizola and Guyot, 2009).

730   According to MGB-SED AS simulations, 2×10^9 t/year of silt and clay leave the hillsides
731 and reach the SA rivers. Of these, about 12% are trapped in the floodplains before reaching the
732 Oceans under natural conditions (i.e., without impoundments). This value can be substantially
733 higher for some regions. As related by Bourgoin et al. (2007) and most recently by Rudorff et al.
734 (2018), the mean trap efficiency for the floodbasin encompassing the Lago Grande de Curuai
735 (lower Amazon River) is 45%-48%. For this region, strong winds can induce waves
736 resuspending fine sediment in dry seasons, when the floodplains and lakes are shallow (Bourgoin
737 et al., 2007; Fassoni-Andrade and Paiva, 2019a; Schmidt, 1972), which means that less sediment
738 is trapped. Despite the importance of the wind effect for this region, it was not considered in the
739 current study. Meanwhile, for the central Amazon floodplains, the trapped value found is one
740 order (~10^7 t/year) bigger than that estimated by Rudorff et al. (2018) only for one reach. It is not
741 possible to make a direct comparison due to the different approaches used in the aforementioned
742 studies.

743   The effect of SS deposition on the floodplains is quite evident in the highlands of
744 Madeira river basin (Figure 10), causing a sharp reduction in SSC values from upstream to
745 downstream. For example, Guyot et al. (1996), using regressions between observed Q and QSS
746 data, estimated a reduction for QSS and SSC of 54% and 95%, respectively in the Mamoré basin.
747 In comparison, we estimated a 35% (75%) increase (decrease) in QSS (SSC). As discussed in
748 section 4.1.2, the main differences can be associated to the methods used to estimate QSS values
749 (regression analysis × sediment modeling), which may be enough to find such different results
750 and patterns.

751   The region assessed on the Mamoré River drains a large amount of sediment originating
752 in the Andes. The same happens with the Pilcomayo River. The Mamoré River flows through
753 regions with dynamic and complex fluvial geomorphology, with avulsion and silting
754 mechanisms of the bed in the Llanos de Moxos floodplain. According to MGB-SED AS
755 simulations, ~2×10^7 t/year of SS are deposited in this floodplain (Figure 10). The Pilcomayo

756   River flows through and floods the flat regions of the Chaco, losing water to the atmosphere
757   through evapotranspiration (Martín-Vide et al., 2014). The Pilcomayo River basin also presents
758   great complexities, similar to those described for the Mamoré River (see Martín-Vide et al.,
759   2014). In the upper Pilcomayo, near the Andes, Martín-Vide et al. (2014) estimated a mean SSC
760   of 15×10^3mg/L, while SCC simulated was 28×10^3mg/L. For Pilcomayo station, Martín-Vide et
761   al. (2014) estimate a QSS of 140 Mt/year, while for the same station ($BIAS$=-20% and
762   NSE=0.23), MGB-SED AS estimate was 96 Mt/year. Guyot et al. (1996) estimated a mean SSC
763   of 13×10^3mg/L in Abapo (Figure 10), about two times higher than estimated by MGB-SED AS
764   (6×10^3 mg/L) and by Buarque (2015), in which it was found 5×10^3 mg/L (personal
765   communication) using a regional model.
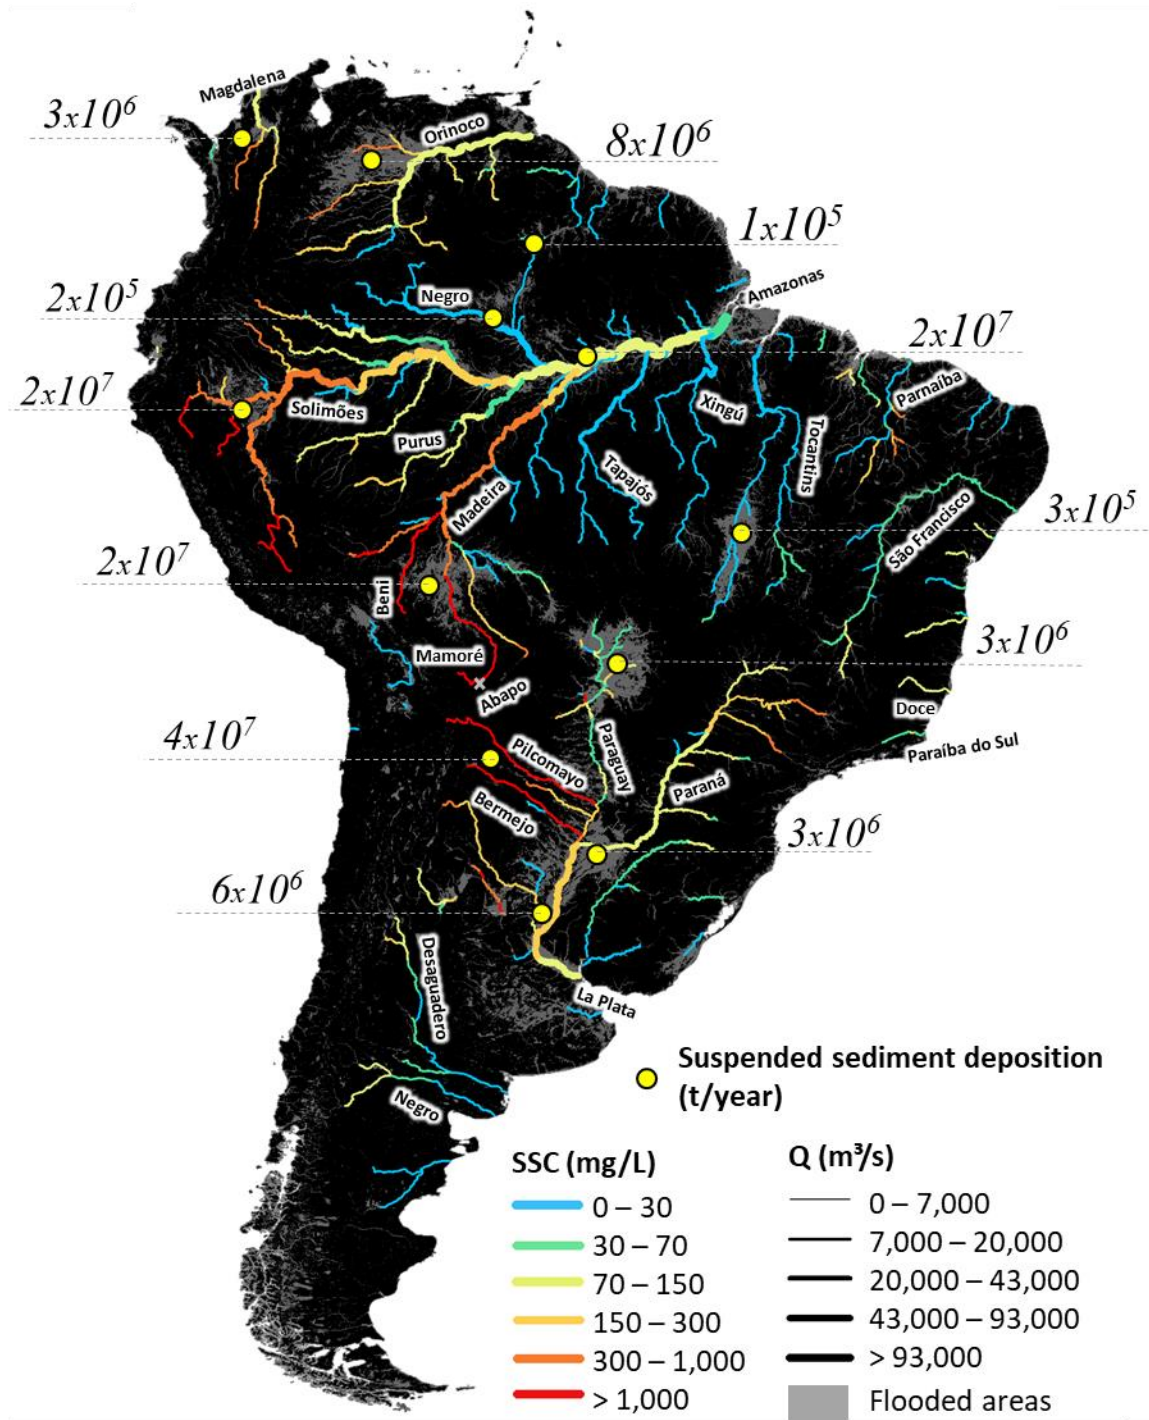

766

767

768

Figure 10: Annual average of suspended sediment load deposited in the main floodplains of South America; long-term daily average of suspended sediment concentration (SSC) and water discharge (Q) for main large rivers. Flooded areas were acquired from Fluet-Chouinard et al. (2015).

MGB-SED SA has estimated lower SSC values in the Mamoré River when compared to Guyot et al. (1996) estimates. The main differences found could be related to the following aspects: i) there was difficulty in calibrating the continental-scale model in the regions of upper Madeira, with the available data; ii) the processes observed in the Andean region, such as

777 landslide-driven sediment flux, are not well represented in the proposed modeling as discussed
778 by Buarque (2015), which shows that significant uncertainties for these regions may exist. The
779 same can occur for other Andes regions, like the headwater of the Pilcomayo, Bermejo and
780 Magdalena rivers.

781   The Pilcomayo River was the only river that showed an increase in concentrations from
782 upstream to downstream (Figure 10). It happens because simulated Q values increase from the
783 upstream to the middle Pilcomayo and decrease again next to the outlet. Martín-Vide et al.
784 (2014) noted that the increase in Q is not proportional to the SSC for the Pilcomayo River. This
785 behavior was identified using MGB-SED AS for the Mamoré River, which differs from the
786 approach used by Guyot et al. (1996). Using the MGB-SED model, which considers several
787 processes and variables and not only Q to estimate the QSS, Buarque (2015) found a NSE=0.7
788 in the Fazenda Vista Alegre station (Madeira River). This indicates that the connection suggested
789 in some studies (e.g. Filizola and Guyot, 2009; Guyot et al., 1996; Lima et al., 2005; Meade et
790 al., 1990; Restrepo et al., 2006), that QSS always increases with Q, cannot always be applied.

791   The assessment in large flooded areas (Figure 10) indicated that 57% of the total SS
792 trapped in the floodplains is deposited in these places. The plains having the highest amounts of
793 deposited SS are the Bañado La Estrella (4×10^7 t/year), Llanos de Moxos (2×10^7 t/year), central
794 Amazon floodplains (2×10^7 t/year) and the interfluvial floodplains of Peru (2×10^7 t/year). In the
795 whole Amazon basin, about 1×10^8 t/year of SS are deposited in floodplains, which corresponds
796 to ~50% of total SS trapped in the floodplains in the whole South America.

797   4.2.3.2 Annual Sediment Balance

798   The impact of model calibration and hydrodynamic routing in South America was also
799 assessed by the suspended loads leaving the continent. When using the hydrodynamic model
800 without calibration, the QSS reaching the oceans was 2.86×10^9 t/year. After calibration, this
801 value was 1.00×10^9 t/year, which means that the calibration of MGB-SED AS provided
802 estimates 65% lower. When the calibration and Muskingum-Cunge routing method were
803 considered, the value increased by 18% (1.18×10^9 t/year). Syvitski et al. (2005) estimated for
804 "prehuman" period that QSS delivered from SA was, on average 2.68×10^9 t/year, a value 268%
805 (6%) higher (lower) than estimated with calibrated (non-calibrated) MGB-SED AS. In their
806 global study on tropical rivers, Syvitski et al. (2014) highlighted that most modeling projects use
807 boundary conditions without considering sediment depositions in the deltas, which could reduce
808 the value of the SS that effectively leaves the continent. In this paper, we partially represent this
809 effect, since the model does not consider coastal basins and islands with A<1,000km² or
810 submerged coastal regions.

811   Naturally (without considering impoundments), the daily water (SS) transport of
812 3.10×10^{10} m³ (2.76×10^6 t) by the SA rivers to the oceans was estimated using MGB-SED AS. Of
813 this total, 57% (43%) of the water (SS) volume comes from the Amazon basin.

814   Figure 11 presents a monthly balance of SS and Q for South America and several of its
815 major rivers. In addition, to expand the understanding of the different relations between Q and
816 SSC, a map with the Delay Index (*DI*) calculated between these two variables is also presented
817 in this figure. Values in red (blue) shades show how many days the SSC peak is ahead (behind)
818 in relation to the Q peak.

819   The *DI* map (Figure 11) shows that the occurrence of the SSC peak earlier than the Q
820   peak is mainly in some Amazon tributaries, Brazilian northeast and areas closer to Atacama
821   Desert. In the Paraná, São Francisco (Figure 11-f), Bermejo, Magdalena (Figure 11-b), Doce
822   (Figure 11-g), and Paraíba do Sul river basins, *DI* values are closer to zero. A common feature of
823   these basins is that they have hilly relief regions and relatively few flat areas, which facilitates
824   the transport of water and sediments to (and along) river channels.

825   Throughout the year, the simulated QSS in SA ranged 3-7$\times10^7$ t/day, in which higher
826   values were occurring between February and June (Figure 11-d). The SS deposition on the
827   floodplains has higher values between November and April.

828   In the Amazon River, the sediment supply (MUSLE) peak was in January, together with
829   the floodplains deposition (Dep) peak, and the QSS peak only occurs in February (Figure 11-a).
830   The Amazon River dynamics is mainly influenced by lateral contributions, which is related to
831   the variation of the rainy periods in the south and north of the basin (Villar et al., 2008). In the
832   south, there is the Madeira River basin with high sediment yield (44% of all Amazonas) and the
833   occurrence of QSS and Q peaks, respectively, in February and April. In the north, there is the
834   Negro River with low sediment yield (1.5% of all Amazonas) and the occurrence of QSS and Q
835   peaks, respectively, in June and July. The Solimões and Madeira rivers is those one that, in fact,
836   control the temporal dynamics of the Amazon River in the outlet. In the Solimões river, the
837   discharge, sediment supply and deposition of SS occur concomitantly in March. Both SSC
838   (Figure 10) and QSS decrease from upstream to downstream in Amazon basin (Solimões-
839   Amazon rivers). The QSS and SSC back to increase from the confluence with Madeira River.

840   The Magdalena River showed two Q peaks (Figure 11-b), where the first peaks are about
841   two months apart (May-July) and the last in about one month (November-December). SS
842   (discharge, sediment supply and deposition on floodplains) also have two peaks, occurring in
843   May and in November, concomitantly with Q peaks. In the La Plata River, the Q and QSS peaks
844   were observed in March and February, respectively. The SS supply peak was observed in
845   February, and about 10% of these sediments are then deposited on floodplains, in which the
846   deposition peak occurs in January (Figure 11-c).

847

The Tocantins (Figure 11-e) and São Francisco (Figure 11-f) river basins have a similar area, are geographic close to each other but have very different sediment flows. The Tocantins River (Figure 11-e) has a large floodplain on the Araguaia River, while the São Francisco River has almost no floodplains (Figure 1). Despite this, the São Francisco river basin has a more deposited SS load than that of Tocantins. This occurs because the São Francisco transports a larger load with lower flows, which facilitates deposition and because the Araguaia River has a lower sediment yield in its headwaters (Figure 8-a). The SS supply, floodplains deposition and transport occur in January to the São Francisco and in March to the Tocantins.

The Doce River presents a straightforward relationship between water discharge and sediments, and similar monthly variations (Figure 11-g). The Q and QSS peaks occur in January, and only about 0.6% of the sediments reaching the drainage network (this value can be zero for dry season) are deposited in floodplains.

Figure 11 shows that in basins with larger flat areas (e.g., Magdalena, Amazonas and La Plata), the SS supply peak occurs concomitantly with the deposition peak. In the Doce and São Francisco river basins, the SS supply peak occurs together with the deposition and also Q peaks. It means that only for the highest flows the SS reach the floodplains of these basins. In the

870   Tocantins river basin, this fact may be related to the low sediment transport in the Araguaia
871   River, which is the main tributary and has the largest flat regions.

872

873

874   **5 Conclusions**

875   In this research, we performed the coupling of the MGB-SED sediment model with the
876   hydrologic-hydrodynamic model of South America (MGB AS). From this coupling, the MGB-
877   SED AS was developed and assessed. Using the model results was possible to investigate and
878   understand temporal and spatial patterns of suspended sediment (SS) flows on a continental
879   scale.

880   The main conclusions related to the process of development, performance evaluation, and
881   application of the model for the comprehension of continental standards are:

882   •   The MGB-SED AS model was able to perform accurate estimates at several sites, which
883   was evaluated against in-situ measurements. The calibration of the model parameters
884   improved the estimates of the SS flows, obtaining an export value from SA, under natural
885   conditions (without impoundments), equivalent to 65% of the values estimated without
886   calibration.
887   •   The use of the hydrodynamic routing method enabled better SS estimates, especially the
888   simulated QSS peaks in places having floodplains. By using the simplified routing method
889   and without floodplains, estimates of annual loads have increased by 18%.
890   •   We observed that the MGB-SED AS results agreed with in-situ observed QSS. The model
891   tends to estimate QSS values smaller than with the estimates from regional studies and the
892   global model used as comparison. The use of the continental model does not exclude the
893   use of models at regional and local scales for smaller-scale studies.
894   •   The Amazon (4.36×10^8 t/year), Orinoco (1.37×10^8 t/year), La Plata (1.11×10^8 t/year) and
895   Magdalena (3.26×10^7) rivers presented the highest suspended sediment yield, meaning
896   44%, 14%, 11% and 3% of total South America discharges values to the ocean. Floodplains
897   play an important role by retaining about 12% (2.40×10^8 t/year) of SS carried by the rivers.
898   About 57% of the total deposition occurs in large flooded areas, for which the Banãdo La
899   Estrella (4×10^7 t/year), Llanos de Moxos (2×10^7 t/year), central Amazon floodplains
900   (2×10^7 t/year) and the interfluvial floodplains of Peru (2×10^7 t/year) representing the four
901   regions with the highest deposition rates.
902   •   The increase in Q does not always result in an increase in SSC/QSS. Especially in rivers
903   with large floodplains, Q and SSC/QSS peaks can occur up to months apart.
904   •   Catchments with higher slopes and higher rainfall have higher SSC, while QSS tends to be
905   higher where flows are higher.

906   Results presented in this work enabled the comprehension of the spatiotemporal dynamics of SS
907   flows in South America. Generated maps present the annual rates of denudation, transport
908   (discharge and concentration), and deposition (in the plains) of SS throughout the continent.
909   Charts of the annual sediment balance were also generated for some rivers chosen as having high
910   sediment transport. These information may be useful for other studies on a continental scale, for
911   example, related to reservoirs, fish productivity, nutrient transport, carbon balance, and other
912   studies related to ecosystem maintenance and soil conservation. Besides, this information can

913 support decision making, planning, and management of continental land use. Studies such as that
914 of Latrubesse et al. (2017) have shown a possible increase of dams in South America in the
915 future. Thus, to have a better knowledge of sediment fluxes in the present, it is necessary to
916 consider these structures in sediment modeling, which is part of the continuation of this research.
