10
Key Points

11
12
- Experiments on a 4-m-long rock fault show two stages of slow slip evolution and foreshock activities preceding main fast rupture.

13
14
- Most foreshocks were triggered by the slow slip at the second stage with a rate faster than 100 µm/s regardless of accumulated slip amount.

15
16
- Magnitude of repeating foreshocks tended to positively correlate with local slip rate in three of four repeater groups.
17

Abstract

We report laboratory experimental results to reveal the factors that control the occurrence and magnitude of foreshocks. We conducted rock friction experiments using an apparatus that can shear 4-meter-long rock specimens. We observed many stick-slip events, as well as very slow (several tens of μm/s) but long-lasting slips between those main events. These long-term slow slips individually initiated from both the leading and trailing edges of the fault, and kept propagating steadily towards each other. Such steady slips did not immediately trigger any seismic events, regardless of the accumulated slip amount. After the coalescence of the two long-term slow slip fronts, a second phase of slow slip with higher slip rate (several hundreds of μm/s) — called precursory slow slip, began at the central area and was accompanied by the occurrence of small seismic events (foreshocks). Subsequently, the main fast rupture eventually developed. We propose that the asperities that hosted foreshocks had similar size to the local critical nucleation length h^*; the asperities slipped stably when the local loading rate was low, but could also slip unstably and radiated seismic waves when the local loading rate became high. We further found a clear positive correlation between foreshock magnitude and local slip rate. These results suggest that local loading rate has a significant influence on the occurrence and magnitude of foreshocks. Therefore, its effect should be taken into account during the studies of earthquake nucleation process and other similar phenomena such as Episodic Tremor and Slip (ETS), icequakes, and repeating earthquakes.

Plain Language Summary

It is known that two contacting surfaces do not perfectly fit with each other, but with very limited areas in actual contact. The real contacting areas are highly stressed and can serve as asperities — a situation thought to also apply to a natural fault. It is also considered that asperities are more difficult to break, but can generate seismic waves once broken. However, the exact conditions when the asperities break are still unclear. To investigate them, we have conducted laboratory experiments with 4-meter-long rock blocks. We observed extremely slow (several tens of μm/s) fault slips during the shear loading stage. While no seismic events occurred during the initial phase, a second phase of slow slips with higher slip rate (several hundreds of μm/s) was often accompanied by the occurrence of small seismic events (foreshocks). We also found that the magnitude of foreshocks became larger under a higher local slip rate. These observations suggest that the asperities on the fault slip stably under the low local loading rate, but can slip rapidly and

49 radiate seismic waves under the high local loading rate. Therefore, it is necessary to incorporate

50 the effect of local loading rate into the studies of natural earthquakes.

1 Introduction

52 To predict when and where the next major earthquake will initiate is of great importance

53 to both scientific research and disaster mitigation. It is well known that unstable fast rupture does

54 not suddenly begin on a fault plane, but is often preceded by a quasi-stable slow slip, which is

55 called the nucleation process. The transition from the slow slip to the fast rupture was first

56 demonstrated by some pioneer laboratory experiments (Dieterich, 1978; Ohnaka & Kuwahara,

57 1990; Okubo & Dieterich, 1984). Ever since those earlier studies, more experimental studies

58 have been conducted to improve the understanding of the nucleation process (e.g. Latour et al.,

59 2013; McLaskey & Lockner, 2014; Nielsen et al., 2010; Ohnaka & Shen, 1999; Gvirtzman &

60 Fineberg, 2021). In parallel, theoretical and numerical studies have also been conducted to

61 investigate the nucleation process and to construct a comprehensive model for it (e.g. Ampuero

62 & Rubin, 2008; Dieterich, 1992; Lapusta & Rice, 2003; Noda et al., 2013; Rubin & Ampuero,

63 2005; Uenishi & Rice, 2003).

64 The length of the slipping region, at which a stable slip transitions to an unstable rupture,

65 is called the critical nucleation length $h*$. Considering the conditions at the seismogenic depth,

66 $h*$ and the associated slip amount expected from the above studies were supposed to be too small

67 to be detected by observations at the Earth's surface. However, recent geodetic observations

68 showed detectable crustal deformations preceding some large earthquakes (Ito et al., 2013; Ruiz

69 et al., 2014, 2017; Socquet et al., 2017), though their behaviors are not so simple as the ones

70 predicted by theoretical models.

71 Another possible way to detect the nucleation process is to monitor seismic activity, i.e.,

72 foreshocks. Although foreshocks do not always occur and are usually classified retrospectively,

73 they can still provide us with valuable information for understanding the earthquake nucleation

74 process. Several studies have reported foreshocks (Bouchon et al., 2013; Ruiz et al., 2017) and

75 their migration (Kato et al., 2012; Ruiz et al., 2014) preceding some large earthquakes. Recent

76 study also showed that even the nucleation process for a very small earthquake (M3.7) can be

77 inferred from the detected foreshock activity, and further suggested that those foreshocks could

78 be triggered by an underlying slow slip on the fault (Tape et al., 2018). However, the exact
79 triggering mechanism is still unknown.

80   Considering the complicated behaviors of earthquake nucleation process and the
81 uncertainty of foreshock detection under a natural condition, laboratory experiment should be
82 one of the best approaches for fully understanding those phenomena. Selvadurai and Glaser
83 (2015) conducted direct shear experiments with PMMA blocks. They observed that high normal
84 stress could suppress the propagation of slow slip and increase the foreshock size, which were
85 reproduced by their numerical simulation. McLaskey and Lockner (2014) conducted friction
86 experiment with saw-cut cylindrical granite samples using a triaxial loading apparatus. They
87 observed accelerated seismic activity before each stick-slip event but found 98% of premonitory
88 moment release was due to aseismic preslip. They proposed that the main stick-slip event was
89 triggered by a cascade-up process assisted by the preslip. McLaskey and Kilgore (2013)
90 observed foreshocks preceding stick-slip events on a 2-m long granite fault. Since the foreshocks
91 only occurred at the final phase in the nucleation process, they proposed that the increased
92 stressing rate during the nucleation caused a reduction of $h*$ and then triggered the foreshocks.

93   Recently, apparatuses for meter-scale rock friction experiments have been newly
94 developed, which can provide more realistic conditions for investigating the earthquake
95 nucleation process than the conventional small-scale experiments since the nucleation zone size
96 can be within the sliding fault area. An apparatus using a large-scale shaking table has been
97 developed and installed at the National Research Institute for Earth Science and Disaster
98 Resilience (NIED) in Japan (Fukuyama et al., 2014). Large-scale friction experiments using this
99 apparatus have been conducted, and effects of fault width (Fukuyama et al., 2018), fault
100 roughness (Yamashita et al., 2018), and loading rate (Xu et al., 2018) on the rupture nucleation
101 process were reported in detail. The research group also demonstrated that foreshocks, the
102 locations of which coincided well with those of generated wear materials, were triggered right
103 after the passage of a precursory slow slip front prior to the main rupture on a less heterogeneous
104 fault (Yamashita et al., 2021). At Cornell University in the U.S., an apparatus that can shear 3-m
105 long granite blocks has been developed. This apparatus successfully produced the initiation,
106 propagation, and also termination of ruptures on the fault, which should be closer to natural
107 earthquakes than the conventional stick-slip events (Ke et al., 2018). Using this apparatus,
108 McLaskey (2019) proposed that the smooth nucleation process predicted by theory is hard to

4

109   occur on natural rough faults, but foreshocks, which are produced during the nucleation process,

110   finally trigger the main dynamic rupture.

111   In this paper, we also investigate the nucleation process of earthquakes in the laboratory,

112   but with an even larger rock fault and much better instrumentations than previous studies. These

113   advantages allow us to quantitatively understand the key factors that control the occurrence and

114   magnitude of foreshocks during the experimentally simulated nucleation process. In the

115   followings, we first introduce the basic experimental setup. Then, we show slow slip activity as

116   part of the nucleation process leading to the main event. Next, we compare the spatiotemporal

117   distribution of foreshocks with that of local slip or local slip rate, and investigate the factors that

118   control the occurrence and magnitude of foreshocks. Finally, we discuss the implications of the

119   obtained results, and make the concluding remarks.

120   **2 Method**

121   2.1 Experimental setup

122   Figure 1a shows a schematic diagram of the newly developed apparatus for the current

123   study. This apparatus enables us to shear 4-meter-long rock specimens. We used a pair of

124   metagabbro blocks from India as the experimental specimen. The physical properties are listed in

125   Table 1. The shorter block was stacked on the longer one as shown in Figure 1a. The nominal

126   contacting area was 4.0 m long and 0.1 m wide, and is treated as the simulated fault in the

127   current study. Normal load was applied with eight flat jacks installed side by side between the

128   top frame of the apparatus and a steel plate on the top surface of the upper specimen. The

129   dimension of a single flat jack was 0.5 m long and 0.1 m wide. The flat jacks were pressurized

130   by the mixed fluid of oil and air in order to keep the pressure constant even if the flat jacks were

131   deformed during an experiment. The pressure of the flat jacks was built up to an objective value

132   before shearing and was maintained at a constant value by shutting each oil circuit off during an

133   experiment. The pressure of each flat jack was separately monitored by a pressure gauge (GP-

134   M100, Keyence Corp., Japan) to estimate the amount of normal stress on the simulated fault.

135   According to a preliminary calibration by the manufacturer of the flat jack, the actual pressure

136   applied by the flat jack is around 67% of its oil pressure, because the edges of the flat jack are

137   not in contact with the pressurized face and thus the total contacting area is inevitably smaller

138   than the whole fault area. To retrieve the actual pressure value, we first averaged the oil

139   pressures over eight flat jacks and then reduced the averaged value to 67%. We treated the

140   obtained value after the 33% reduction as the macroscopic normal stress (σ) on the simulated

141   fault. Shear load was applied by a hydraulic jack installed at the western end of the apparatus.

142   The western end of the lower specimen was loaded by this jack. The lower specimen was put on

143   a low-friction roller on the bottom frame, so that only the simulated fault supported the shear

144   load. The amount of shear load was measured with a load cell (CLP-2MNS006, Tokyo

145   Measuring Instruments Laboratory Co., Ltd., Japan) installed between the hydraulic jack and the

146   lower specimen. Therefore, the amount of macroscopic shear stress (τ) was obtained from the

147   measured shear load divided by the fault area.

148

149   **Table 1** *Properties of rock specimen*

Item	Property
Rock type	Metagabbro
Dimension for upper specimen	L4.0 m x W0.1 m x H0.2 m
Dimension for lower specimen	L4.1 m x W0.1 m x H0.2 m
Nominal dimension of contacting area	L4.0 m x W0.1 m
Initial undulation of contacting surface	< 10 μm
Young's modulus	103 GPa
Poisson's ratio	0.31
P-wave velocity*	6919 m/s
S-wave velocity*	3631 m/s

150   *Seismic wave velocities were estimated from Young's modulus, Poisson's ratio, and density.

Figure 1. Experimental setup in this study. (a) Schematic diagram of rock friction apparatus at NIED. An upper rock specimen is vertically stacked on a lower rock specimen. Normal load is applied by eight flat jacks inserted side by side between upper frame of the apparatus and the

155 upper specimen. Oil pressures of the flat jacks are maintained at a constant value by closing the
156 oil circuit during an experiment. Shear load is applied by laterally pushing the lower specimen
157 with a hydraulic jack. The amount of normal stress (σ) on the simulated fault is assumed to be
158 67% of the averaged oil pressure of eight flat jacks. The amount of shear stress (τ) is estimated
159 from the amount of load measured with a load cell. Map view of the upper specimen indicating
160 the locations of (b) 16 acoustic sensors (AS) and (c) 40 triaxial semiconductor strain gauges
161 (SGT). (d) Map view of the lower specimen indicating the location of 10 eddy current gap
162 sensors (GAP). (e) Side view showing the configurations of various sensors. The target of GAP
163 is installed on the side surface of the upper specimen.

164

165   We repeated the experiments with the same pair of rock specimens (named FB02) under

166 the same normal stress around 4 MPa. Because we manually pumped up the hydraulic jack to

167 apply the shear load in the experiments, the loading rate was not well controlled. Nevertheless,

168 we tried to keep the shear loading rate as uniform as possible, but also with fast or slow rates in

169 order to investigate the influence of macroscopic loading rate on the fault rupture process. In the

170 current study, we investigate two experiments FB02-006 and FB02-008 with relatively high

171 shear loading rate, as well as two other experiments FB02-007 and FB02-010 with relatively low

172 loading rate. See Table 2 for the actual loading rate in each experiment. Because of the effective

173 range of eddy current gap sensor described in the next section, the total amount of displacement

174 during a single experiment was limited within 2 mm. Five experiments have been done before

175 FB02-006. It is supposed that some amount of wear materials was produced on the fault. The

176 wear materials were kept on site throughout all the experiments.

177

178 **Table 2** *Macroscopic shear loading rate and local slip rate during long-term slow slip*

Experiment ID	Macroscopic shear loading rate (kPa/s)	Slip rate at GAP01 during long-term slow slip (µm/s)
FB02-006	92.7±15.5	11.8±3.4
FB02-007	3.5±1.7	0.7±0.3
FB02-008	163.4±28.5	19.5±9.5
FB02-010	4.7±1.5	1.5±0.6

179

180   2.2 Measurements

181   Signal from the load cell was processed with a strain amplifier (CDV-71A, Kyowa

182 Electronic Instruments Co., Ltd., Japan). The oil pressure of the pressure gauge for the flat jack

183 was output as electrical signals. Those signals were continuously sampled at 1 MHz with 16-bit

184 resolution (M2i4741-mgt, Spectrum Instrumentation, Germany). In addition to the macroscopic

185 monitoring, we installed 16 broadband acoustic sensors (V103-RM, Olympus Corp., Japan)

186 named AS, 40 triaxial semiconductor strain gauges (SKS-30282, Kyowa Electronic Instruments

187 Co., Ltd., Japan) named SGT, and 10 eddy current gap sensors (FK-202F, Shinkawa Electric

188 Co., Ltd., Japan) named GAP along the fault, in order to monitor the local phenomena on the

189 fault in detail (Figures 1b-1e). ASs were installed on both side surfaces of the upper specimen,

190 70 mm away from the simulated fault (Figures 1b and 1e). AS has a resonance frequency at 1

191 MHz and the signal was amplified 20 times by a custom-made amplifier (Turtle Industry Co.,

192 Ltd., Japan). The amplified signal was continuously sampled at 10 MHz with 14-bit resolution

193 (M2i4032, Spectrum Instrumentation, Germany). SGTs were installed on both side surfaces of

194 the upper specimen, 10 mm away from the simulated fault (Figures 1c and 1e). Three strain

195 gauge components were offset by 45, 90, and 135 degrees from the horizontal fault plane as

196 shown in Figure 1e. The strain signal from each component was individually processed with a

197 signal conditioner (CDA-700A or CDA-900A, Kyowa Electronic Instruments Co., Ltd., Japan)

198 and continuously sampled at 1 MHz with 16-bit resolution (M2i4741-mgt, Spectrum

199 Instrumentation, Germany or PXIe-6358, National Instruments Corp., USA). GAP can measure

200 the relative horizontal displacement between the edge of a probe and a steel target. The probe

201 was fixed by an aluminum holder glued on the side surface of the lower specimen. The steel

202 target was glued on the side surface of the upper specimen (Figure 1e). This transducer has a flat

203 sensitivity up to 10 kHz, and the signal was continuously sampled at 50 kHz with 24-bit

204 resolution (LX-120, TEAC Corp., Japan). The measurement range of GAP was from 0.25 mm to

205 2 mm.

206 **3 Basic results**

207   In every experiment, stick-slip events were observed, which is consistent with the

208 velocity-weakening behavior of metagabbro in the framework of the rate- and state-dependent

209 friction (RSF) law reported by a previous study (Urata et al., 2017). In order to compare the

210   results of the four experiments under a similar condition, we picked up the last seven stick-slip

211   events right before the total amount of slip reached 2 mm and then named those events evt-1 to

212   evt-7. Figures 2a, 2d, 2g, and 2j show the evolution of macroscopic τ/σ for the last seven events.

213   The macroscopic loading rate shown in Table 2 was obtained from the averaged trends during

214   the shear loading stage before each stick-slip event.

215   Seismic signals associated with the stick-slip events are presented in Figures 2b, 2e, 2h,

216   and 2k. Those panels show the sum of squared amplitude over all AS channels (on a logarithmic

217   scale) during a 0.1 ms time interval. High value of the sum means a large seismic energy release

218   at the time. Colored cross symbols represent detected repeating seismic events, which will be

219   explained in Section 4.4. We detected local peaks of the calculated sum and then picked up a

220   time-window like the one in Figure 3. Figures 3a and 3b show the records of AS and those of

221   shear stress (converted from SGT) over the same time period, respectively. As seen, a small

222   seismic event (sevt) was clearly captured by both the AS array (Figure 3a) and the SGT array
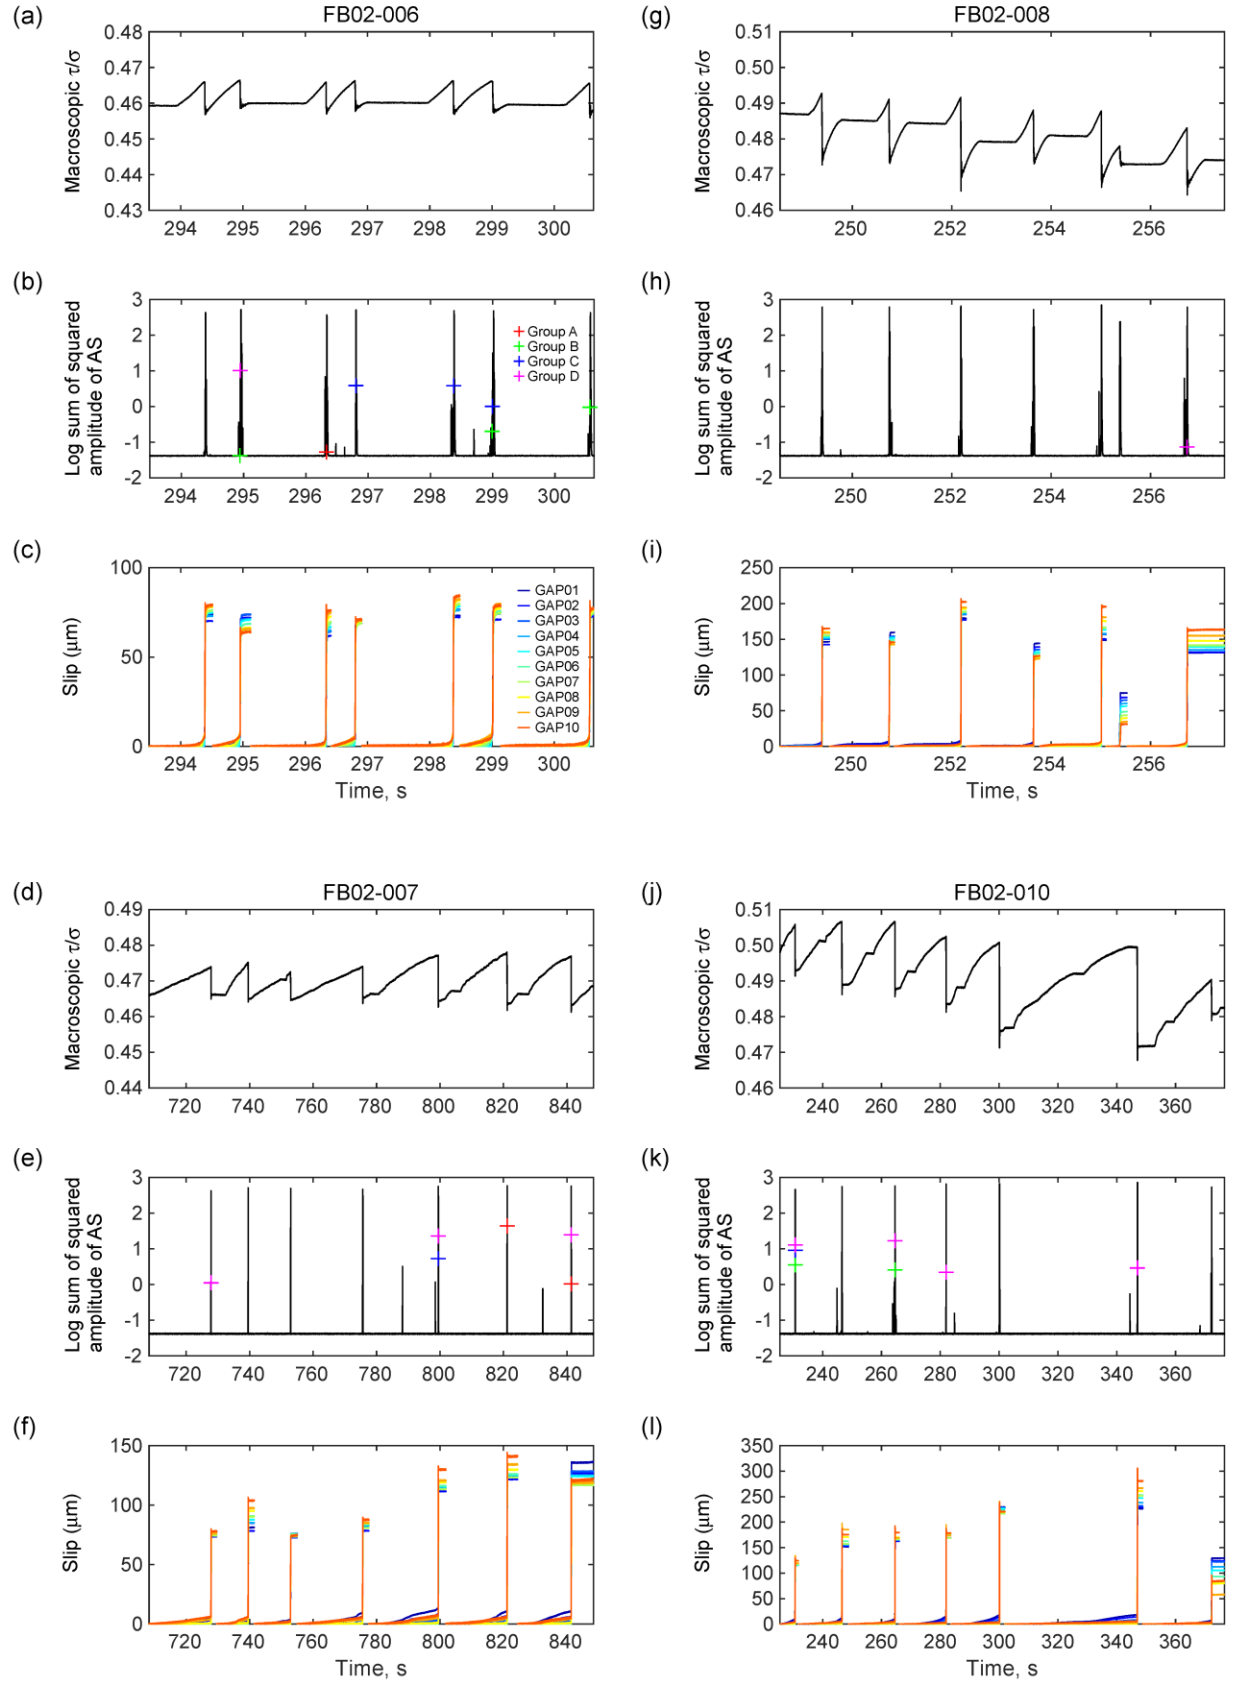

223   (Figure 3b).

Figure 2. (a) Macroscopic τ/σ, (b) logarithmic sum of squared amplitude of AS output, and (c) amount of slip for experiment FB02-006. (d)-(f) Similar to (a)-(c) but for experiment FB02-007. (g)-(i) Similar to (a)-(c) but for experiment FB02-008. (j)-(l) Similar to (a)-(c) but for experiment FB02-010. Cross symbols in (b), (e), (h), and (k) indicate the occurrence time of repeating foreshocks (see section 4.4). The amount of slip at each channel in (c), (f), (i), and (l) is reset to zero after each main stick-slip event.

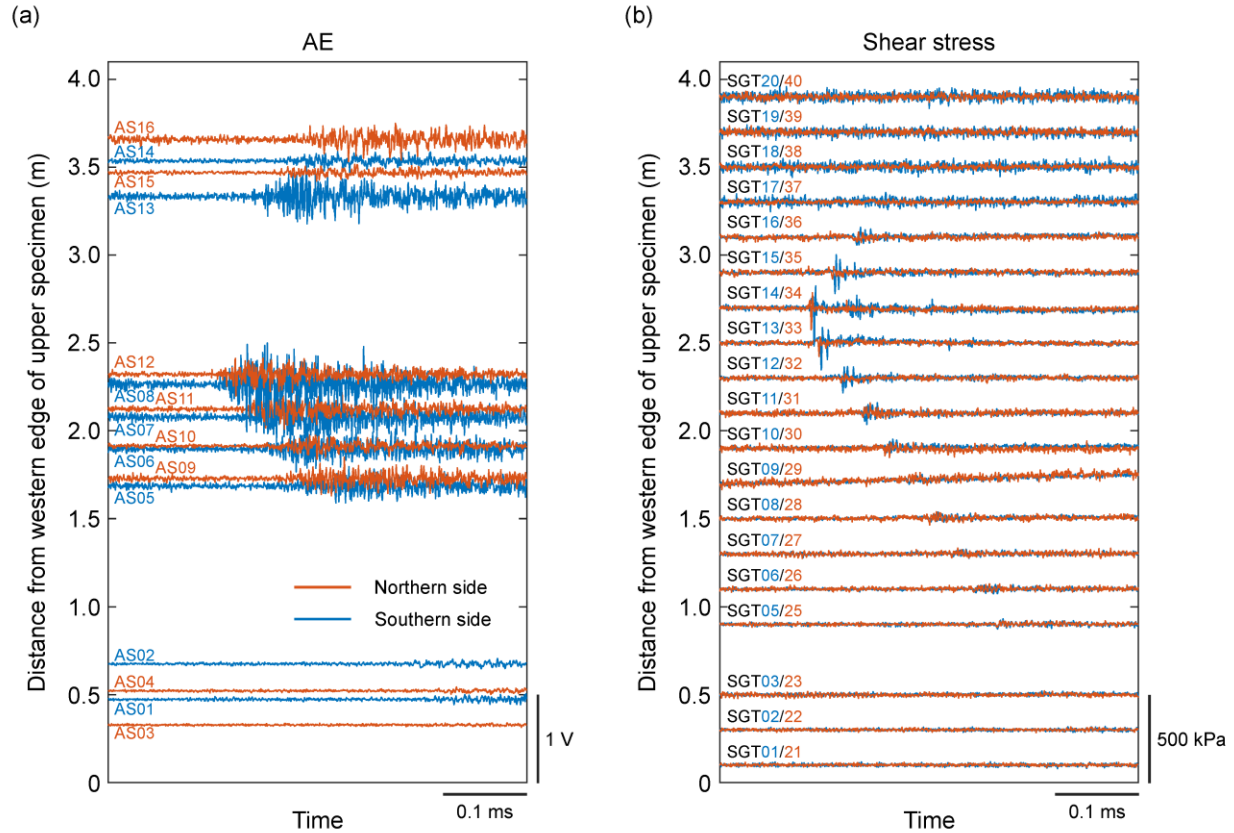

Figure 3. Typical foreshock waveforms observed by (a) the acoustic sensor AS array and (b) the strain gauge SGT array over the same time period. The waveform in (b) shows shear stress along the fault, which was calculated from the measured strain. Data of SGT04 and SGT24 are not displayed because of their abnormal values caused by a local crack in the rock specimen. The label at the left end of each waveform indicates the location of the associated sensor.

Figures 2c, 2f, 2i, and 2l show the fault slips between and during the stick-slip events. Note that the amount of slip was reset to zero after every stick-slip event in these panels. The total amount of slip over a single stick-slip cycle was around 100 μm on average. It should be noted that the slips at both the leading and trailing edges were gradually increasing even at the shear loading stage, which is more significant in the experiments with low loading rate (FB02-007 and FB02-010). Figure 4a shows the detailed spatiotemporal distribution of slip along the

245   fault in a stick-slip cycle, where dense and sparse contour lines represent slow and fast slip

246   during different stages of the stick-slip event, respectively. Figure 4b shows the early-stage

247   evolution of local fault slip before the main slip event, which clearly reveals that both the leading

248   and trailing edges began to slip at first and kept slipping for a long time; we call this slip

249   behavior "long-term slow slip" in this study. Comparison between the macroscopic loading rate

250   and the local slip rate suggests that this long-term slow slip is dominantly controlled by the

251   macroscopic shear loading (see Table 2 and Appendix A.2). The slipped areas gradually enlarged

252   toward the central area of the fault, and then fast slip was initiated after the two slipped areas

253   coalesced at the along-fault location of ~ 1.7 m. Figure 4c shows the slip evolution after the

254   coalescence, which is called "precursory slow slip" in this study. We will discuss why and how

255   the long-term slow slip was generated in section 4.1, and will examine the relation between

256   seismic activity and local slip activity in sections 4.2, 4.3 and 4.4.
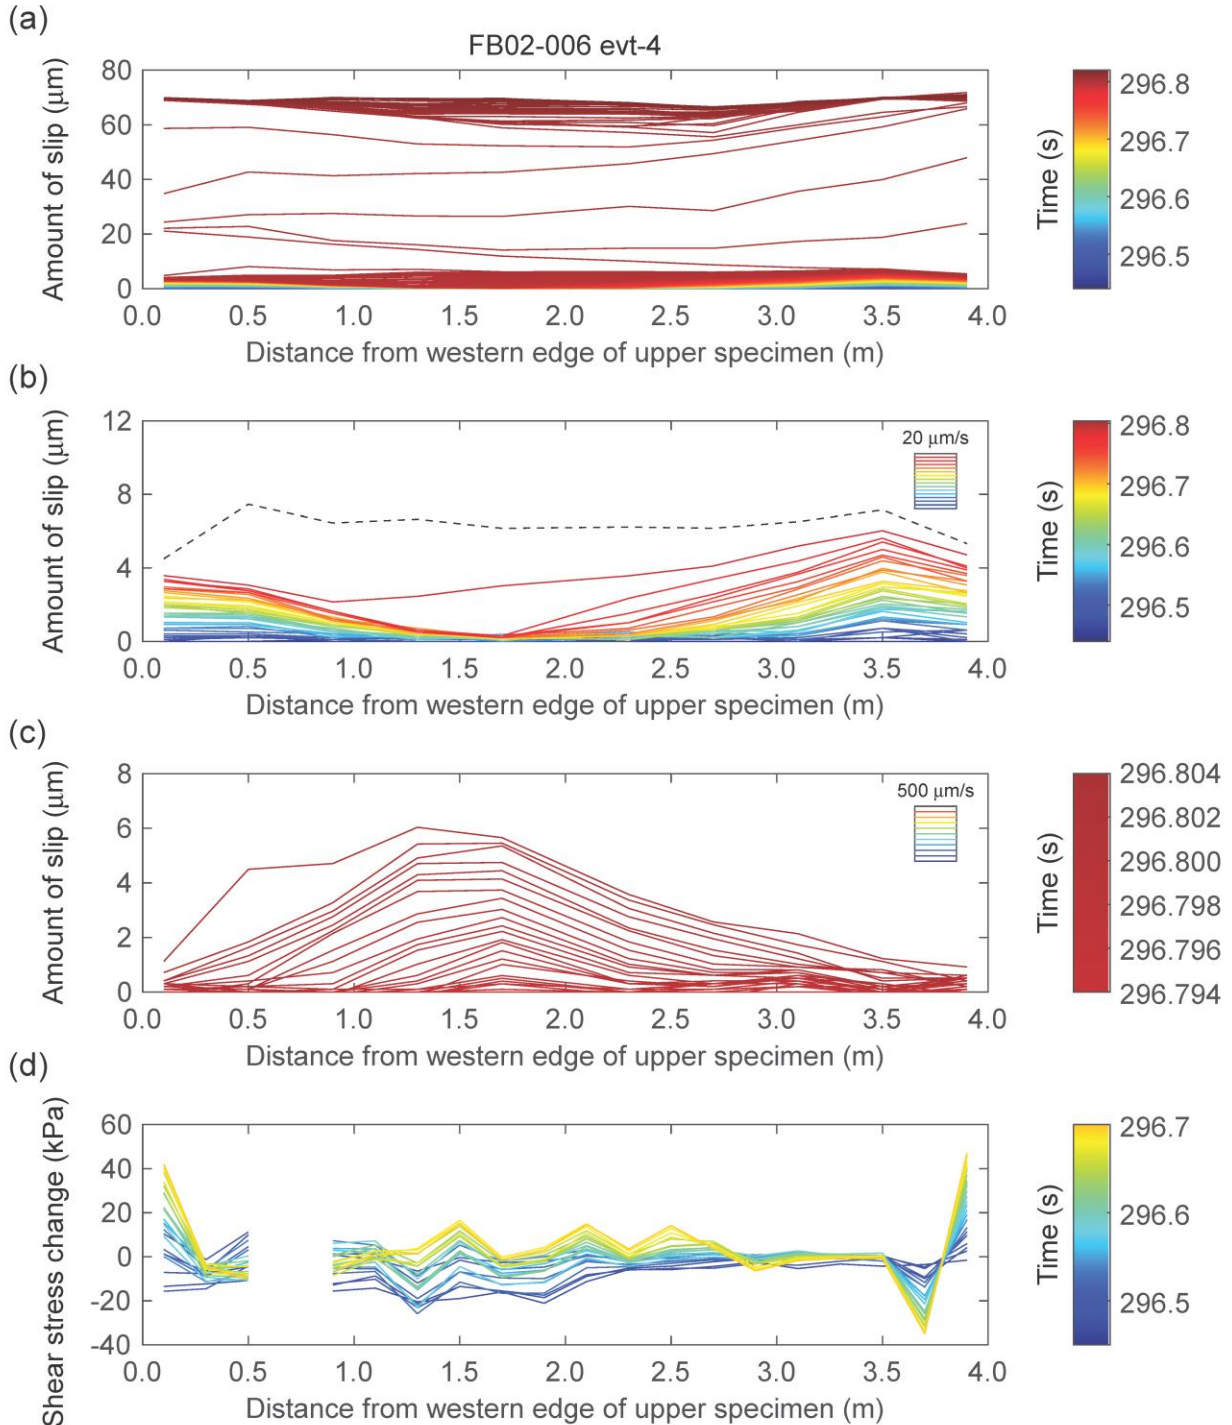

257

Figure 4. (a) Spatiotemporal evolution of slip along the fault for a stick-slip event evt-4 in FB02-006. Contour lines are drawn every 0.4 ms. The amount of local slip was reset to zero after the previous event evt-3. (b) Enlarged view of the amount of local slip until the initiation of the main fast slip. Contour lines are drawn every 10 ms. Black dashed line indicates the amount of slip at the moment when the main fast slip initiated (see Appendix A.1 for the procedure of detecting the moment). (c) Slip evolution during the last 10 ms time window right before the initiation of the main fast slip. The amount of local slip was reset to zero at the beginning of this 10 ms time

14

266 window. Contour lines are drawn every 0.4 ms. (d) Change in the local shear stress from 296.45
267 s to 296.70 s estimated from the northern strain gauge array (SGT21 - SGT40). The amount of
268 shear stress was reset to zero at the beginning of this time window. Contour lines are drawn
269 every 10 ms. The data of SGT24, which was installed at 0.7 m from the western edge, was
270 removed from this plot because of its abnormal value caused by a local crack in the rock
271 specimen. Colors of contour lines indicate time, and the indexes are common among (a), (b), (c),
272 and (d).

273

274 **4 Detailed analyses**

275 4.1 Long-term slow slip

276 In order to understand why the long-term slow slip initiated from both edges of the fault
277 (Figure 4b), we conducted a finite element method (FEM) modeling. We used a FEM program,
278 Salome-Meca produced by EDF (Électricité de France, http://www.code-aster.org). This
279 program composed of a pre- and post-processor SALOME and a solver Code_Aster. Figures 5a-
280 c show a model constructed for the FEM calculation. This model consisted of vertically stacked
281 rock blocks and a steel plate on the upper rock block, whose dimensions were the same as those
282 for real specimens and part of the apparatus in the current experiments. Note that only the
283 southern half of the system was modeled because of the symmetry in the north-south direction.
284 Young's modulus and Poisson's ratio for the steel plate were 200 GPa and 0.30, respectively,
285 and those for the rock blocks were shown in Table 1. The contacting interfaces between the
286 upper and the lower rock blocks had a static friction coefficient of 0.75. We divided this model
287 into 357,783 elements, the shape of which was tetrahedron except for regions around the
288 contacting interfaces. In order to make rectangular mesh on the interfaces, quadrangular-
289 pyramid-shaped elements were arranged there. The maximum mesh size was 25 mm and that on
290 the contacting interfaces was 5 mm. Because of the symmetry, a fixed boundary condition was
291 applied to the northern side face of the model in the north-south direction (Figure 5b). At the top,
292 6-MPa-pressure was applied at eight rectangular regions on the steel plate, to simulate the
293 normal load from the eight flat jacks to the fault (Figure 5c). The bottom face of the lower rock
294 block was fixed in the up-down direction (Figure 5c). The eastern side face of the upper rock
295 block was also fixed in the east-west direction (Figures 5b and 5c). After applying the normal
296 load, we gradually increased the shear load to the western side face of the lower rock block
297 (Figures 5b and 5c).

Figure 5. Configuration of FEM calculation for the current experimental setup and the results. View of the mesh model from (a) diagonally above, (b) top, and (c) south. Only the southern half was modeled because of symmetry. Evolutions of (d) the local slip and (e) the local τ/σ distribution with increasing the macroscopic shear stress obtained from the FEM calculation. Dashed line in (e) represents τ/σ of 0.75, which is the static friction coefficient of the contacting interfaces defined in the FEM calculation. Features of the slip initiations and the increase in shear stress from both edges of the fault are consistent with the observations shown in Figures 4b and 4d, respectively.

308   The calculated evolutions of local slip and τ/σ are shown in Figures 5d and 5e, which

309   simulated the situations when the macroscopic τ/σ increased from 0.05 to 0.30. Note that

310   displayed slip and τ/σ were averaged values along the north-south axis. As shown in Figure 5e,

311   the local τ/σ increased and attained the assumed static friction coefficient at both edges, which

312   led to the local fault slips as shown in Figure 5d. With increasing the applied shear load and thus

313   macroscopic τ/σ, the slipped area expanded toward the central locked area from both edges,

314   which is similar to the observed behavior shown in Figure 4b. We also note that the calculated

315   evolution of τ/σ (Figure 5e) is also similar to the observed shear stress evolution (Figure 4d).

316   4.2 Foreshock activity and accumulated slip

317   The occurrence times of seismic events, as roughly estimated from the AS amplitude

318   (Figures 2b, 2e, 2h, and 2k), suggest that most of the small seismic events occurred right before

319   the main stick-slip events (see Figure B1 for a close-up view of FB02-006 evt-1). Therefore, they

320   can basically be categorized as "foreshocks". We defined the seismic events that occurred in the

321   second half of recurrence time since the previous stick-slip event as foreshocks and then focused

322   on their activities in the current study. Based on the seismic record, we determined the origin

323   time and hypocenter location of the foreshocks (See Appendix B.1 for the procedure). Figure 6

324   shows the located hypocenters of the foreshocks. The numbers of located foreshocks for FB02-

325   006, FB02-007, FB02-008, and FB02-010 are 47, 28, 32, and 54, respectively, which suggests

326   that foreshock activity is not directly relevant to the macroscopic loading rate (Table 2) in the
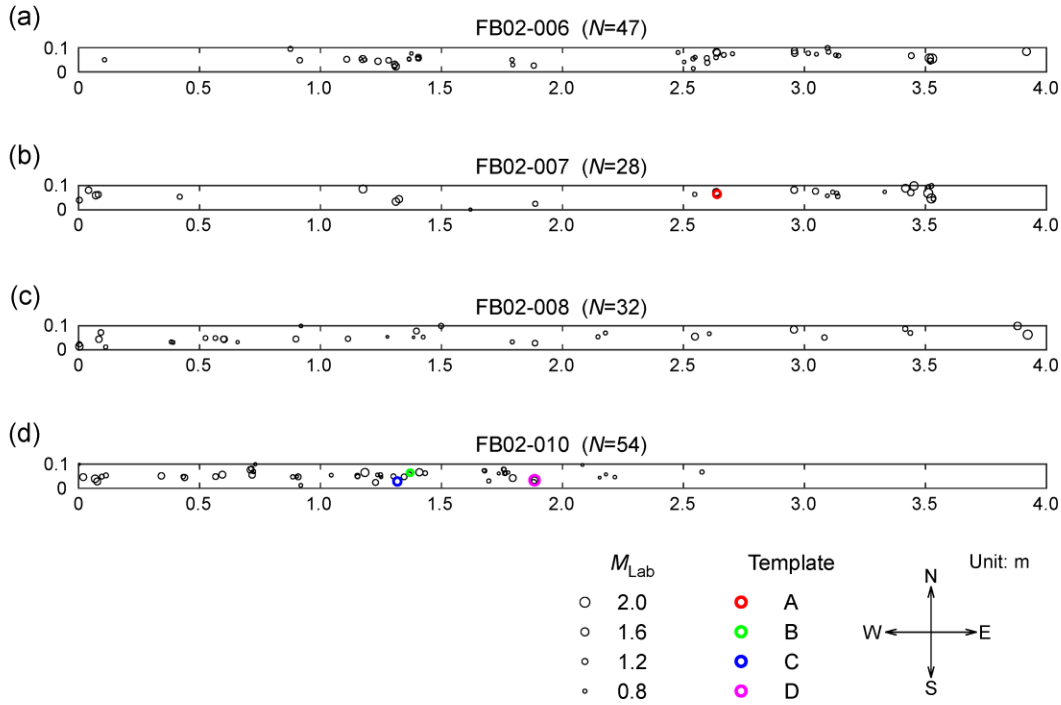

327   current experiments.

Figure 6. Hypocenters of foreshocks for (a) FB02-006, (b) FB02-007, (c) FB02-008, and (d) FB02-010. The size of circles scales with the laboratory-specific magnitude (M_{Lab}) of foreshocks. The colored circles indicate the hypocenters of template foreshocks (see section 4.4).

Based on the foreshock catalog, we investigated the relationship between foreshock activity and local slip activity. Figure 7a compares spatiotemporal distribution of the foreshocks with that of the local slip right before a main stick-slip event (evt-5) in the experiment with low loading rate (FB02-007). Note that the shown result represents the amount of slip accumulated after the previous main stick-slip event (evt-4). There exists a significant variation in the accumulated slip along the fault: the accumulated slip reached more than 10 µm at the western edge whereas it was almost zero at the central area. Figure 7a also shows that foreshocks occurred right before the main stick-slip event (black dashed line), regardless of the amount of accumulated slip there. This situation is common among other events including the case with high loading rate, for example FB02-008, as shown in Figure 7b.
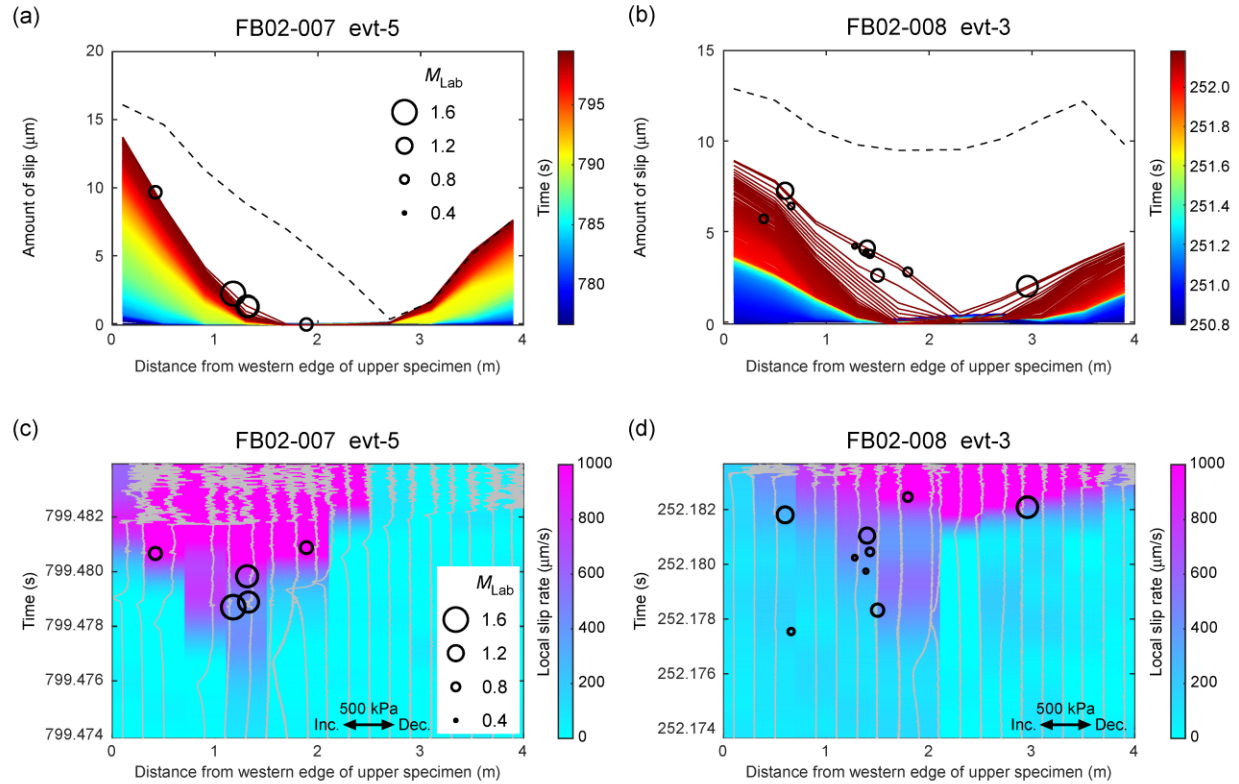

Figure 7. Comparison between spatiotemporal distribution of the foreshocks and that of the slip accumulated after the previous stick-slip event right before the initiation of the main fast slip for (a) evt-5 in FB02-007 and (b) evt-3 in FB02-008. Contour lines are dawn every 20 ms for (a) and 2 ms for (b). Black dashed line indicates the amount of slip at the moment when the main fast slip initiated. The amount of accumulated slip shows no clear correlation with the occurrence of the foreshocks. Comparison between spatiotemporal distribution of the foreshocks and that of the slip rate during a 10 ms time window right before the initiation of the main fast slip for (c) evt-5 in FB02-007 and (d) evt-3 in FB02-008. Gray lines show changes in shear stress estimated from the northern strain gauge array (SGT21 - SGT40). Bottom end of each gray line indicates the location where the associated strain gauge was installed. Foreshocks occurred when the local slip rate reached at several hundreds of µm/s.

4.3 Foreshock activity and local slip rate

Next we compared the spatiotemporal distribution of the foreshocks with that of the local slip rate. To obtain the slip rate, we calculated the time derivative of slip measured by each GAP sensor. Color map in Figure 7c shows the distribution of the calculated slip rate. Note that the slip data were smoothed with splines before the calculation of time derivative just for clear view in this figure. Gray lines show changes in shear stress estimated from the northern SGT array (SGT21-SGT40). The strain data show temporal increase and subsequent decrease in the shear

363 stress and its outward propagation from the central area, which should represent a nucleation

364 process. An example for the slip evolution during the nucleation process (called precursory slow

365 slip) is already shown in Figure 4c, which is a common feature among the nucleation processes

366 of many other events. The local slip rate increased with the progression of the nucleation

367 process, and then the foreshocks occurred when the local slip rate reached at several hundreds of

368 µm/s. This situation is also common for the experiment with high loading rate (Figure 7d).

369   In order to quantify the relationship between foreshock occurrence and local slip rate, we

370 estimated the local slip rate around the site of foreshock hypocenter, $\dot{D}_{loc}$ (See Appendix A.3 and

371 Figure A3 for the estimation), which was obtained by spatial interpolation. Figure 8 shows a

372 histogram of foreshocks as a function of the estimated $\dot{D}_{loc}$. As clearly demonstrated, the number

373 of foreshocks is significantly high between 100 µm/s and 1000 µm/s of $\dot{D}_{loc}$.

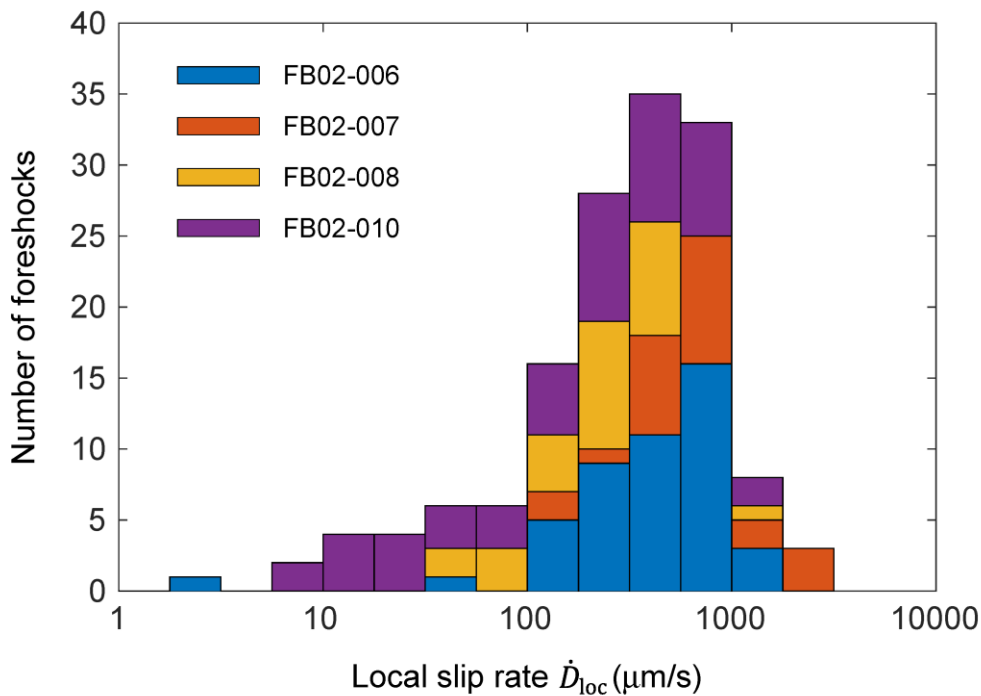

374

Figure 8. Histogram of foreshocks as a function of local slip rate $\dot{D}_{loc}$ estimated at the same site
376 and time. The number of foreshocks increases rapidly when $\dot{D}_{loc}$ exceeds 100 µm/s.

377

378   4.4 Foreshock magnitude and local slip rate

379   We next investigated the relationship between foreshock magnitude and local slip rate.

380 We first simply compared a laboratory-specific magnitude M_{Lab} (See Appendix B.1) with $\dot{D}_{loc}$,

381   which resulted in a weak positive correlation between them as shown in Figure 9a (correlation

382   coefficient between common logarithm of $\dot{D}_{\text{loc}}$ and M_{Lab} equals 0.22). Here, it should be noted

383   that this comparison was performed over all the foreshocks, at different locations, with various

384   magnitudes, and under different loading conditions. In order to focus on the specific role of local

385   slip rate and to exclude other effects, we searched for foreshocks that repeatedly occurred at the

386   same location over four experiments by adopting the matched filter technique (MFT; See

387   Appendix B.2 for the procedure). MFT has been widely used for detecting various seismic events

388   such as low-frequency earthquakes (Shelly et al., 2007), aftershocks (Peng & Zhao, 2009), and

389   foreshocks (Kato et al., 2012). Here we assume that the status of each location that could host

390   repeating foreshocks was stable throughout the four experiments. As the result of MFT, we

391   identified four groups of repeating foreshocks (See Figures 2b, 2e, 2h, 2k, 6, and Table B1). We

392   then compare the magnitude of the repeating foreshocks with $\dot{D}_{\text{loc}}$.

393   For the foreshock magnitude, we have already obtained M_{Lab} as a laboratory-specific

394   magnitude. However, it should be noted that the estimation might not be precise enough for

395   capturing a subtle variation in the magnitude of the repeating foreshocks. For example, error in

396   the hypocenter location can affect the estimation because the distance between the hypocenter

397   and the station is included in its calculation as shown in eq. (B.4). Therefore, for more robust

398   comparison, we estimated the relative magnitude of the foreshock M_{r} based on the amplitude

399   ratio of the waveforms (see Appendix B.3 for the procedure). Figures 9b-e compare the

400   estimated M_{r} with $\dot{D}_{\text{loc}}$. Those figures show a clear positive correlation between them except for

401   Group B (correlation coefficients between common logarithm of $\dot{D}_{\text{loc}}$ and M_{r} for Group A, B, C,

402   and D are 1.00, -0.44, 0.72, and 0.50, respectively).

Figure 9. (a) Comparison between the local slip rate $\dot{D}_{loc}$ and the laboratory-specific magnitude M_{Lab}. Correlation coefficient between common logarithm of $\dot{D}_{loc}$ and M_{Lab} is 0.22. Comparison between the local slip rate $\dot{D}_{loc}$ and the relative magnitude M_r for (b) Group A, (c) Group B, (d) Group C, and (e) Group D. Correlation coefficients between common logarithm of $\dot{D}_{loc}$ and M_r for Group A, B, C, and D are 1.00, -0.44, 0.72, and 0.50, respectively.
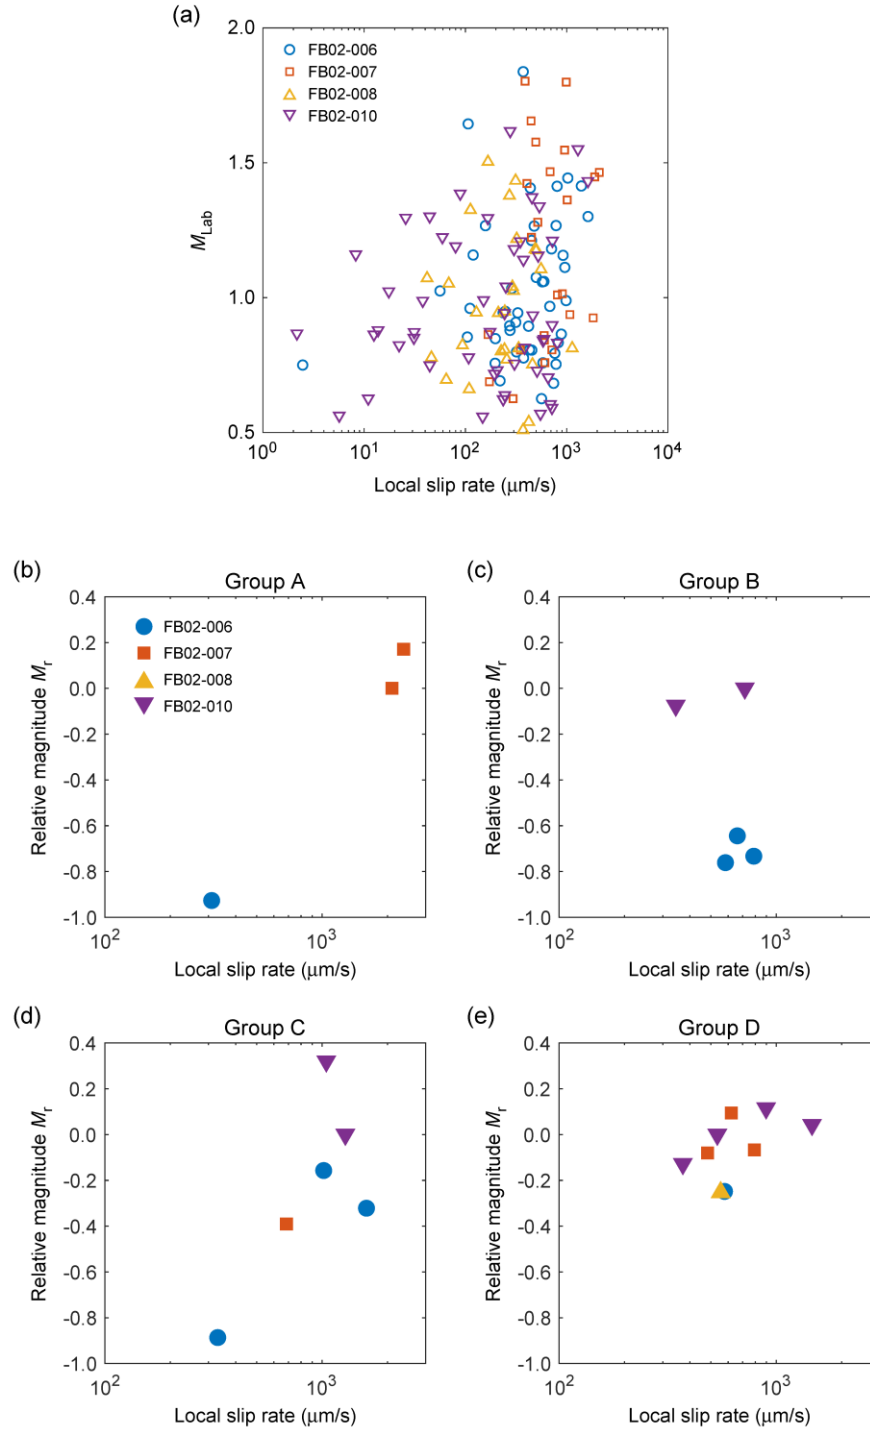

409   **5 Discussion**

410   5.1 The cause of long-term slow slip and its characteristics

411   We have conducted rock friction experiments using the newly developed apparatus. The

412   most distinctive feature of this apparatus is that it can shear 4-m-long rock specimens, which

413   could cause unique phenomena such as the long-term slow slip shown in Figure 4b. We observed

414   that the long-term slow slip individually initiated from both the leading and trailing edges of the

415   fault and the slipped areas gradually expanded toward the central fault area before most of the

416   main stick-slip events. This behavior is quite consistent with the results of the FEM calculation

417   as shown in Figures 5d and 5e. It is well known that local normal and shear stresses can

418   concentrate at around edges of a laboratory fault by the edge effect (e.g. Kammer et al., 2015),

419   even if the macroscopic normal load is homogeneously applied. Such stress concentrations can

420   cause a distorted local stress distribution like the ones shown in Figures 4d and 5e. Therefore, it

421   can be considered that the basic features (e.g., location, duration, stability) of the long-term slow

422   slip are derived from stress heterogeneity (generated by specimen geometry and loading

423   configuration). Especially, the strong dependence of local slip evolution on the macroscopic

424   shear loading (Table 2 and Figure A2) suggests a stable nature for the long-term slow slip. We

425   suspect the reason is that the slow slip evolved toward the central area of the fault where the

426   stored shear strain was relatively low (Figure 4d and Figure 5e), which could cause long-lasting

427   slip evolution without immediate instability even on the fault with a velocity-weakening

428   frictional property (in the framework of RSF). This is quite similar to the stable growth of non-

429   interacting mode-I wing cracks under compression, where the flaw-induced mode-I stress

430   intensity factor scales with the background loading but decreases with the length of the wing

431   cracks (Ashby & Sammis, 1990). In addition, we also consider that the rheological property of

432   fault rocks can contribute to the long-lasting stable slip. According to the compiled data and the

433   proposed physical model in Aharonov and Scholz (2018), the steady-state rock friction behaves

434   as velocity strengthening up to a critical thermal velocity V_t (~ 10-100 µm/s), independent of the

435   sign of the RSF parameter *b-a*. Beyond V_t, thermal heating effect will become evident. In our

436   case, the rate of long-term slow slip seldom reached 100 µm/s, implying that the velocity-

437   strengthening fault rheology could also act to impede the acceleration of the long-term slow slip.

438   Similarly, a recent experimental study has also invoked the involvement of viscous-type

439   dissipation for understanding the initial stable growth of nucleation front (Gvirtzman &

440   Fineberg, 2021). All in all, we conclude that stress heterogeneity and fault rheological property

441   are responsible for generating the stable fault slip.

442   5.2 Accelerated slip following the coalescence of multiple slip patches

443   In the current experiments, precursory slow slip with much higher slip rate (several

444   hundreds of µm/s) developed, following the coalescence of two long-term slow slip fronts.

445   Apparently, the coalescence of multiple slip patches has the potential to cause accelerated slip.

446   Indeed, similar phenomenon has been documented by numerical simulations (Fukuyama &

447   Madariaga, 2000; Kaneko & Ampuero, 2011), by experimental studies on a laboratory fault

448   along the anti-plane direction (Fukuyama et al., 2018), and by natural observations of slow slip

449   events on the Cascadia subduction zone (Bletery & Nocquet, 2020). Other similar examples

450   include the sudden increase of fault slip during the surface breakout of a forward-propagating

451   rupture, which can be considered as due to the coalescence of the forward-propagating rupture

452   front with its backward-propagating mirror (Dieterich, 1979; Xu et al., 2015), and to a lesser

453   extent, the coalescence of tensile and/or shear cracks during rock fracture experiments (Bobet &

454   Einstein, 1998; Renard et al., 2019). The aforementioned phenomena may be explained by the

455   intense stress concentrations between approaching rupture/crack tips and the subsequent rapid

456   relaxation of those stress concentrations (Fukuyama & Madariaga, 2000). From a kinematic

457   point of view, they may also be explained by applying a slip-length scaling relation to an

458   increased patch length (Dieterich, 1979; Bletery & Nocquet, 2020), or by invoking the full-crack

459   and half-crack models (Xu et al., 2015). Given the above examples under a variety of conditions,

460   it appears that the coalescence of multiple slip patches (or multiple cracks) through an increased

461   range of elastic interaction could serve as a generic mechanism to cause large events and

462   unstable failure.

463   5.3 Asperity and loading rate on it

464   The detected repeating foreshocks suggest that small asperities, which could slip unstably

465   and radiate seismic waves, persistently existed and repeatedly slipped in a similar way on the

466   fault surface over the current four experiments (Figures 2b, 2e, 2h, and 2k). We presume that

467   those asperities originated from tiny topographic undulations on the fault at first. Stress

468 concentration around the undulations facilitated the generation of wear materials (fault grooves

469 and gouge) during frictional slip, which could further enhance the degree of stress concentration

470 via a positive feedback loop (Yamashita et al., 2015). Consequently, some gouge bumps may

471 have already been formed during the previous experiments on the fault surface, and they could

472 play the role of seismic asperities especially for relatively large foreshocks. In fact, well-

473 correlated distributions of generated gouge and hypocenters of small seismic events have been

474 reported in a previous study (Yamashita et al., 2021), and hence can support our above

475 presumption.

476   Unfortunately, AS output is not calibrated in the current study and therefore the absolute

477 seismic scale cannot be obtained. As an alternative, below we roughly estimate the foreshock

478 magnitude by referring to previous studies. Regarding the foreshock-like seismic events

479 observed on a meter-scale laboratory fault, it has been reported that their typical moment

480 magnitude ranged from -7.0 to -5.0 (McLaskey et al., 2014; Yamashita et al., 2021). We consider

481 that the foreshocks observed during the current experiments fall into a similar range of

482 magnitude. By applying the Brune's model (Brune, 1970),

483     $$\Delta\sigma = \frac{7}{16}M_0 r^{-3} \qquad (1),$$

484 with the definitions of seismic moment M_0 as

485     $$M_0 = \mu D(\pi r^2) \qquad (2)$$

486 and moment magnitude (M_w) becomes

487     $$M_w = \frac{2}{3}\log_{10}(M_0) - 6.067 \qquad (3),$$

488 where $\Delta\sigma$ is the stress drop, r is the source radius, D is an average seismic slip, and μ is the shear

489 modulus (39.3 GPa) calculated from the Young's modulus and the Poisson's ratio in Table 1. A

490 typical D for a foreshock in the current experiments ranges from 0.048 μm to 0.48 μm. Here we

491 assumed $\Delta\sigma$ of 1 MPa, which is the standard value for seismic events observed in a previous

492 meter-scale experiment also using metagabbro specimens (Yamashita et al., 2021). Even for the

493 largest possible foreshock in the current study ($M_w \sim$ -4.4, when r equals half fault width, 0.05 m

494 with the assumption of $\Delta\sigma$ of 1 MPa), D equals only 0.93 μm. Considering these significantly

495 small amounts of D relative to the accumulated slip shown in Figures7a and 7b, the asperities

496   that hosted foreshocks could not be locked completely but probably slipped stably/episodically at

497   their periphery during the long-term slow slip.

498   Before discussing the observed relationship between local slow slip rate and foreshock

499   activity, the physical meaning of local slip rate should be clarified. Recalling the interpolated slip

500   rate $\dot{D}_{\mathrm{loc}}$ at the site of asperity, it is natural to consider that $\dot{D}_{\mathrm{loc}}$ was not exactly the same as the

501   actual slip rate on the asperity (which was partially locked at the time). In this sense, the local

502   slip rate in the region surrounding the asperity should be a proxy of local loading rate applied to

503   the asperity. For the above reason, we mainly use the term "local loading rate" to discuss the

504   influence on foreshock activity in the following sections.

505   5.4 Dependence of foreshock occurrence on local loading rate

506   To understand the positive correlation between $\dot{D}_{\mathrm{loc}}$ (as a proxy of local loading rate) and

507   the foreshock occurrence (Figures 7c, 7d, and 8), it is crucial to investigate the critical nucleation

508   length $h*$ and its dependence on other parameters. In the framework of RSF law (Dieterich,

509   1992), $h*$ can be expressed as

510    $$h^* = \frac{\mu D_c}{\sigma(b-a)}$$ (4),

511   where D_c is the characteristic slip distance over which friction evolves and b-a is the frictional

512   parameter that controls the slip stability with a change in slip velocity. It should be noted that $h*$

513   is inversely proportional to σ. According to Urata et al. (2017), the estimated values of RSF

514   parameters b-a and D_c for a meter-scale metagabbro laboratory fault are 0.0014 and 0.3 µm,

515   respectively. Inserting these values into Eq. (4) results in an $h*$ value of 2.1 m under 4-MPa-

516   normal stress, which seems consistent with the macroscopic slip behavior (Figures 4c, 7c, and

517   7d). If we assume that the real contact area on the fault is 1/1000 to 1/100 of the nominal fault

518   area (Dieterich & Kilgore, 1996), which corresponds to a local normal stress on the asperity of

519   100 to 1000 times of the macroscopic one, and if we also assume that Eq. (4) is still applicable to

520   the real contact area, then the local $h*$ becomes 2.1 to 21 mm, which is comparable to the

521   asperity size (5.2 to 52 mm in diameter for M_w from -7.0 to -5.0, respectively, under the

522   assumption of Δσ of 1 MPa) in the current experiments. Although the theoretical expression of

523    $h*$ is still under investigation in the presence of stress/frictional heterogeneity, a recent numerical

524   simulation has shown that the above discussion is reasonable (Schaal & Lapusta, 2019).

525　　　　Besides the dependence on normal stress, it has also been shown by both experimental

526　　(e.g. Guérin-Marthe et al., 2019; Kato et al., 1992; Xu et al., 2018) and numerical studies (e.g.

527　　Kaneko et al., 2016) that $h*$ can shrink with the increase of loading rate. We also consider that

528　　the local loading rate on an asperity increased with the slip rate in the surrounding region, which

529　　could shrink the $h*$ of the asperity and hence could promote an unstable slip (Figure 10). This

530　　scenario is similar to the one studied by McLaskey and Yamashita (2017). Furthermore, it is also

531　　supported by the results of a recent numerical simulation (Schaal & Lapusta, 2019), the transient

532　　behaviors of seismicity modulated by a nearby major earthquake (Cheng & Ben-Zion, 2019;

533　　Hatakeyama et al., 2017), and the correlation between local slip rate and tremor activity on the

534　　Cascadia subduction zone (Bartlow et al., 2011).

535　　　　We also consider the rheological property (Aharonov & Scholz, 2018) mentioned in

536　　section 5.1 as a possible alternative mechanism for the foreshock occurrence at high local

537　　loading rate. The velocity-strengthening friction below the thermal velocity V_t can help store

538　　elastic energy on the asperities, which later can be rapidly released during the transition to

539　　velocity-weakening friction when local slip rate crosses V_t. The sudden increase in the number of

540　　foreshocks shown in Figure 8 might be related to the transition of frictional regime.

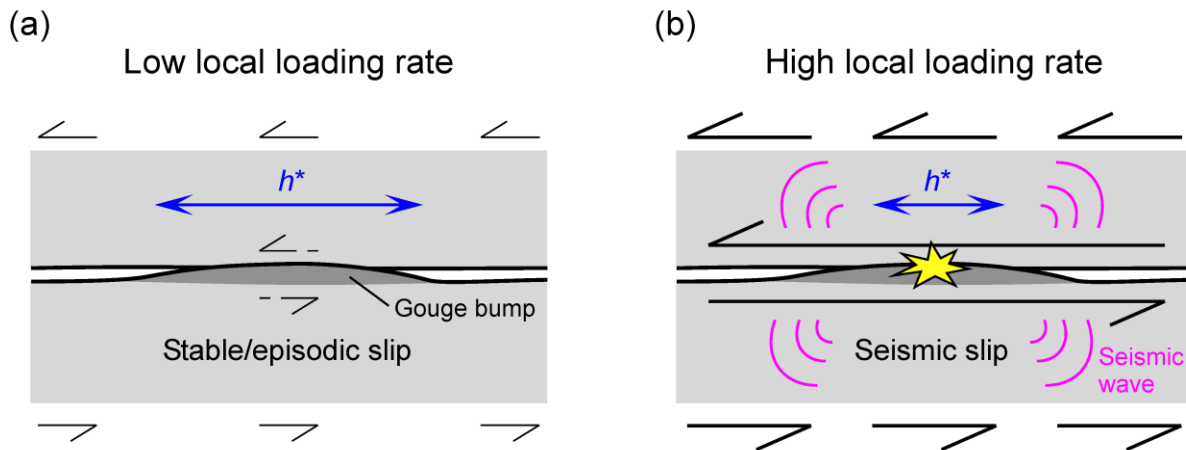

541

542　**Figure 10.** Schematic illustration of foreshock activity controlled by local loading rate. (a) Case
543　for low local loading rate. The contacting asperity made of gouge bump could slip stably or
544　episodically, because the critical nucleation length $h*$ is comparable to or larger than the asperity
545　size. (b) Case for high local loading rate. The asperity can slip abruptly and seismically because
546　$h*$ shrinks and becomes smaller than the asperity size due to the fast loading.

547

548   5.5 Dependence of foreshock magnitude on local loading rate

549   The current experimental results clearly show a positive correlation between the

550   foreshock magnitude and the local loading rate (Figures 9b, 9d, and 9e), except for Group B

551   (Figure 9c). We suspect that the lack of a clear correlation in Group B could be derived from a

552   change in the size of relevant asperities between the experiments FB02-006 and FB02-010. We

553   also note that Figure 9c actually shows a positive correlation within each experiment (in FB02-

554   006 or in FB02-010), which suggests that the size of asperities might not change during each

555   experiment and the dependence of foreshock magnitude on the local loading rate is still valid.

556   Considering the definition of seismic moment expressed in Eq. (2), either the amount of

557   seismic slip or the source dimension needs to increase with the local loading rate, in order to

558   match the positive correlation between the foreshock magnitude and the local loading rate. In

559   fact, a previous experimental study has shown that high loading rate not only can enhance the

560   efficiency for accumulating stress during the shear loading stage (by suppressing concurrent

561   diffusional process such as aseismic slip), but also can promote more efficient energy release

562   during the slip stage (Xu et al., 2018). Similarly, a numerical study of repeating earthquakes has

563   shown that high loading rate can enlarge the source region for accumulating slip deficit, which

564   ultimately will lead to a larger co-seismic rupture area as well as a larger amount of co-seismic

565   slip (Yoshida et al., 2015). While we could not reveal the individual change(s) in foreshock

566   source properties (slip, source area) by our current instrumentations, we think the loading rate

567   effects mentioned above may apply to our experiments. We will continue the investigation of the

568   relation between foreshock magnitude and loading rate in our future studies. Especially, denser

569   acoustic and displacement sensor arrays and direct imaging technique can help achieve a more

570   complete understanding of the topic.

571   5.6 Implications for natural earthquake sequences

572   Elevated seismicity rate and its migration before and after a large earthquake are

573   sometimes detected and reported in nature (e.g. Kato et al., 2012; Peng & Zhao, 2009). It is often

574   interpreted that those seismic activities are driven by the propagation of aseismic slow slip and

575   they occur at the slip front. However, if the situation in nature is similar to that in the current

576   experiments, the slip front would have already passed through a potential asperity and then the

577   associated seismic event on it may be activated by the surrounding slip with an elevated rate. In

28

578 other words, the migration front of seismicity could lag behind the actual slow slip front (see also

579 the discussion in Bartlow et al. (2011)), which would then support the idea of treating asperities

580 as strong-but-brittle sticky spots — an equivalent term used in the field of icequakes (Podolskiy

581 & Walter, 2016, and references therein). If that is the case, using the observed seismic events to

582 estimate the actual slow slip front may cause some errors. Further investigation of the space-time

583 relation between the seismic events and the slow slip will be needed in nature and laboratory.

584   As another example, creep or slow slip on a tectonic fault are often estimated based on

585 the activities of repeating earthquakes (Uchida, 2019; Uchida & Bürgmann, 2019, and references

586 therein). In those analyses, it is basically assumed that the asperities hosting repeating

587 earthquakes are locked during the stick phase and the related seismic moment positively scales

588 with the recurrence interval. However, if the seismic moment can be influenced by the local

589 loading rate as shown by the current study, the estimated amount of creep or slow slip may

590 contain some errors, especially for the situation right before or after a major earthquake, where

591 locally elevated loading rate can decrease the recurrence interval and increase the magnitude of

592 repeating earthquakes. Therefore, the analytical/empirical method(s) for analyzing repeating

593 earthquakes may need to be improved by taking into account the effect of local loading rate.

594 **6 Conclusions**

595   We have conducted rock friction experiments using a newly developed large-scale

596 apparatus that can shear 4-m-long rock specimens. We gradually increased shear load with

597 normal stress kept at around 4 MPa, and observed many stick-slip events. The local displacement

598 data showed that slips individually initiated from both the leading and trailing edges and kept

599 propagating toward the central fault area during the long shear loading stage in each stick-slip

600 cycle. After the coalescence of two long-term slow slip fronts, faster slow slip as part of the

601 nucleation process began at the central fault area and eventually led to main fast rupture over the

602 fault. FEM calculation confirmed that the basic features of the long-term slow slip were derived

603 from stress heterogeneity generated by the experimental configuration. Examination of foreshock

604 activity and local slip data showed that foreshocks could occur regardless of the amount of

605 accumulated slip. On the other hand, foreshocks were often observed when the local slip rate

606 reached around 100 μm/s during the nucleation process. We propose that there exist asperity

607 areas on the fault, whose size is similar to the local critical nucleation length h^*. Those asperities

608   slip stably when the local loading rate is low, but can also slip unstably and radiate seismic

609   waves when the local loading rate becomes high, due to the shrinkage of $h*$ by the fast loading.

610   We also found a clear positive correlation between the relative magnitude of repeating

611   foreshocks and the local loading rate. Our results suggest that the local loading rate has a

612   significant influence on the occurrence and magnitude of foreshocks. Therefore, its effect should

613   be taken into account during the studies of earthquake nucleation process and other similar

614   phenomena such as Episodic Tremor and Slip (ETS), icequakes, and repeating earthquakes.

615   **Appendix A: Fault slip activity**

616   A.1 Onset of main fast slip

617   To discuss the slip behaviors preceding the main fast fault rupture, the onset of the fast

618   slip needs to be specified. We determined it based on the slip acceleration. We first low-pass

619   filtered the slip data with a cut-off frequency of 5 kHz to remove the high-frequency noise, and

620   then calculated the first- and second-time derivatives of the slip for obtaining the slip velocity

621   and acceleration, respectively. We considered the time when the acceleration first exceeded a

622   threshold as the beginning of the fast slip. In this study, we used six times the standard deviation,

623   which was obtained from the slip acceleration in the stable period, as the threshold. We searched

624   for the time in each channel and regarded the earliest time in all channels as the onset of the main

625   fast slip. Figure A1 shows an example for the detected onset of the fast slip.
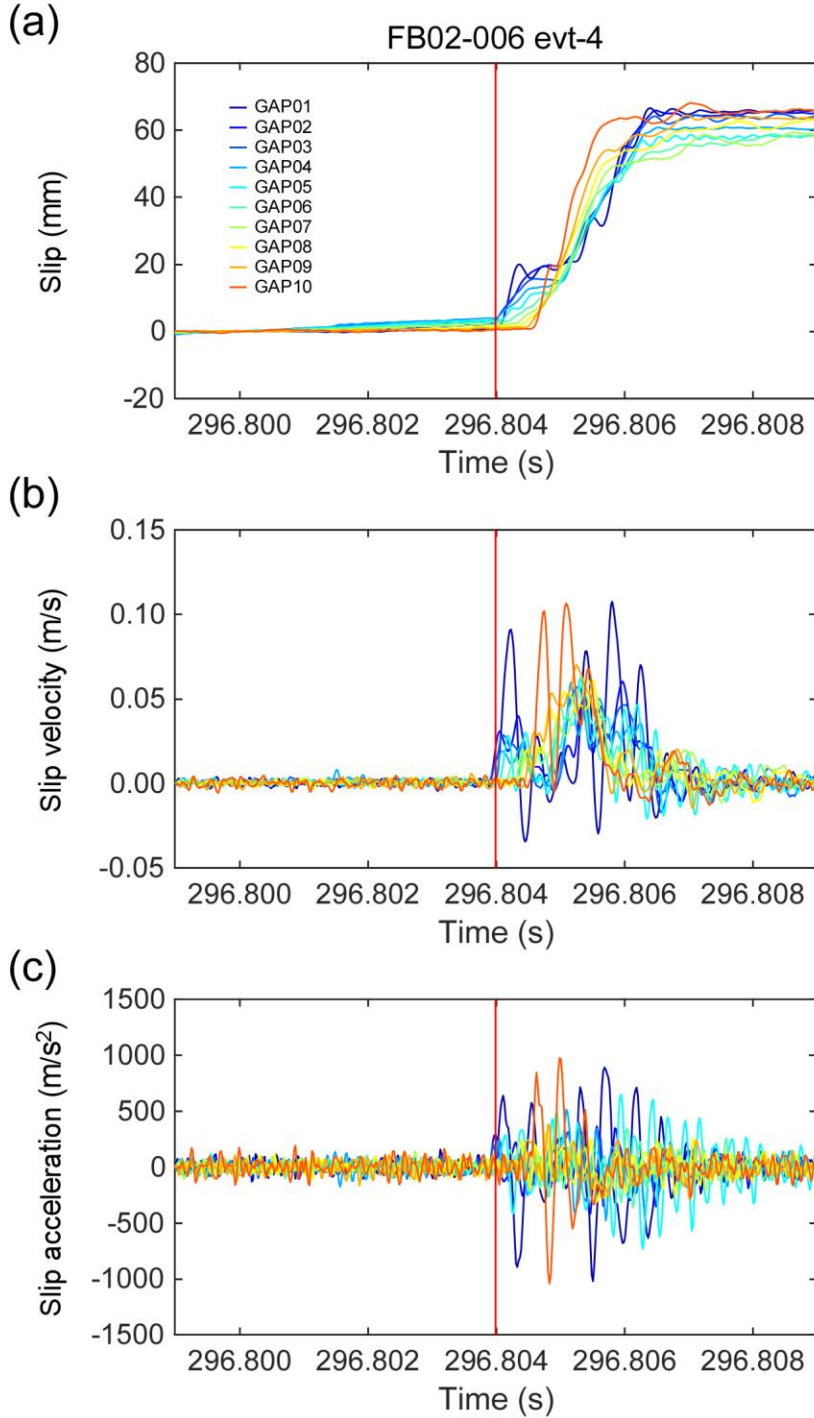

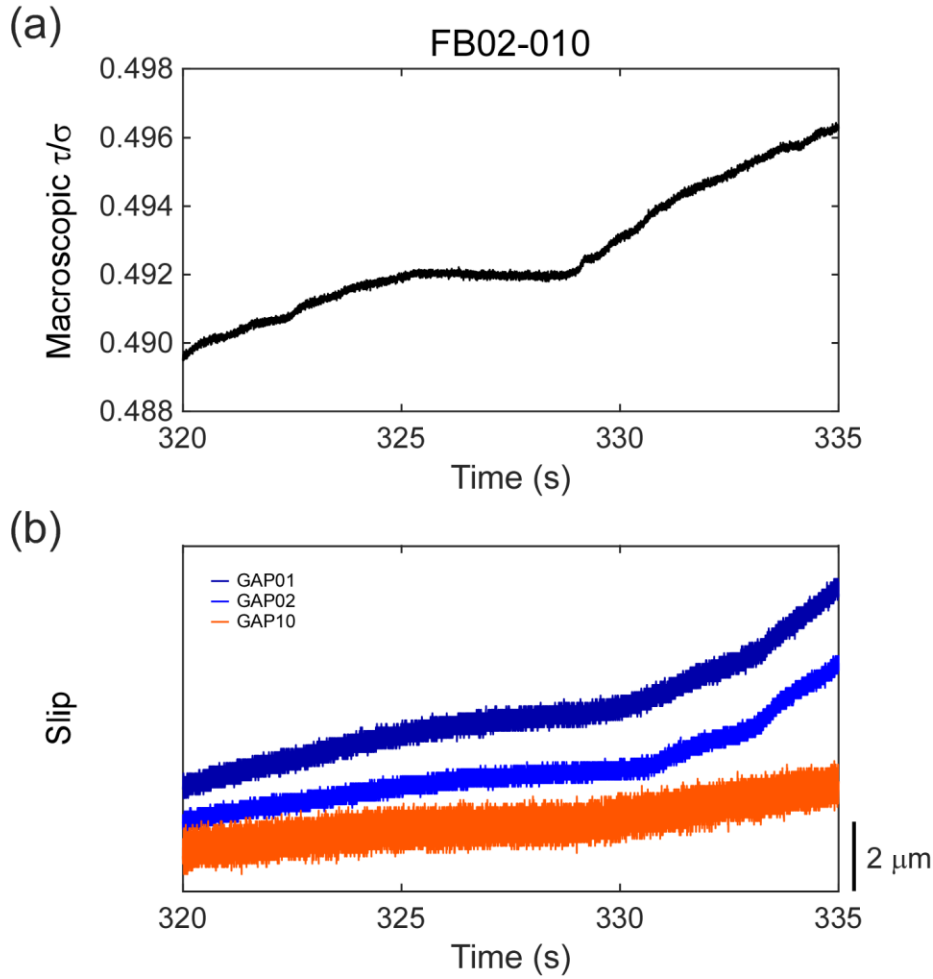

Figure A1. Detection of the onset of the main fast slip. (a) Slip, (b) slip velocity, and (c) slip acceleration before and during a stick-slip event evt-4 in FB02-006. The slip data was low-pass filtered with a cut-off frequency of 5 kHz before calculating the velocity and the acceleration. The specified moment of the onset of the main fast slip is indicated with the vertical red line in (a), (b), and (c).

631   A.2 Dependence of long-term slow slip on shear loading

632   Since the shear load was manually built up, it was unsmooth and sometimes suspended

633   during the loading, which is pronounced in the slow-loading experiments (Figures 2d and 2j).

634   Figure A2a is a close-up view that shows such a temporal suspension of the shear loading in a

635   time period much before the stick-slip event (Figure 2j). Figure A2b shows the slip data at both

636   the edges (GAP01, GAP02, and GAP10) during the same time period as Figure A2a, and it also

637   shows temporally-slowed slip evolution synchronized with the temporal suspension of shear

638   loading. Clear positive correlations between the macroscopic shear loading rate and the local slip

639   rate at GAP01 can be seen in Table 2 too. These features suggest a strong dependence of the

640   long-term slow slip on the shear loading.

641

Figure A2. (a) Temporal suspension of shear loading during FB02-010. The intermittent shear loading is caused by the manual pumping. (b) Behavior of local slip at GAP01, GAP02, and GAP10 during FB02-010. The time period is the same as Figure A2a. The increasing rate of slip is slowed down during the temporal suspension of shear loading.

646

647   A.3 Local slip rate $\dot{D}_{loc}$

648   In order to quantitatively investigate the relationship between the local slip rate and the

649   foreshock occurrence, we estimate the amount of local slip rate at the same site and time as the

650   foreshock. Figure A3 shows the records of GAP for 1 ms before and after the occurrence of a

651   foreshock sevt-20 in FB02-006. In this case, the foreshock was located between GAP03 and

652   GAP04. We fitted a linear line to each record for 2 ms at both neighboring GAP stations and

653   determined each trend, which corresponds to the slip rate at each GAP station. We then linearly

654   interpolated the slip rate at the foreshock hypocenter under the assumption of one-dimensional

655   slip distribution along the fault. Since slip data at both neighboring GAP stations are needed for

656   this estimation, the local slip rate for the foreshock that occurred outside of GAP array was not

657   estimated. We name this spatially-interpolated local slip rate $\dot{D}_{\mathrm{loc}}$. Figure 8 shows a histogram of

658   foreshocks as a function of $\dot{D}_{\mathrm{loc}}$.
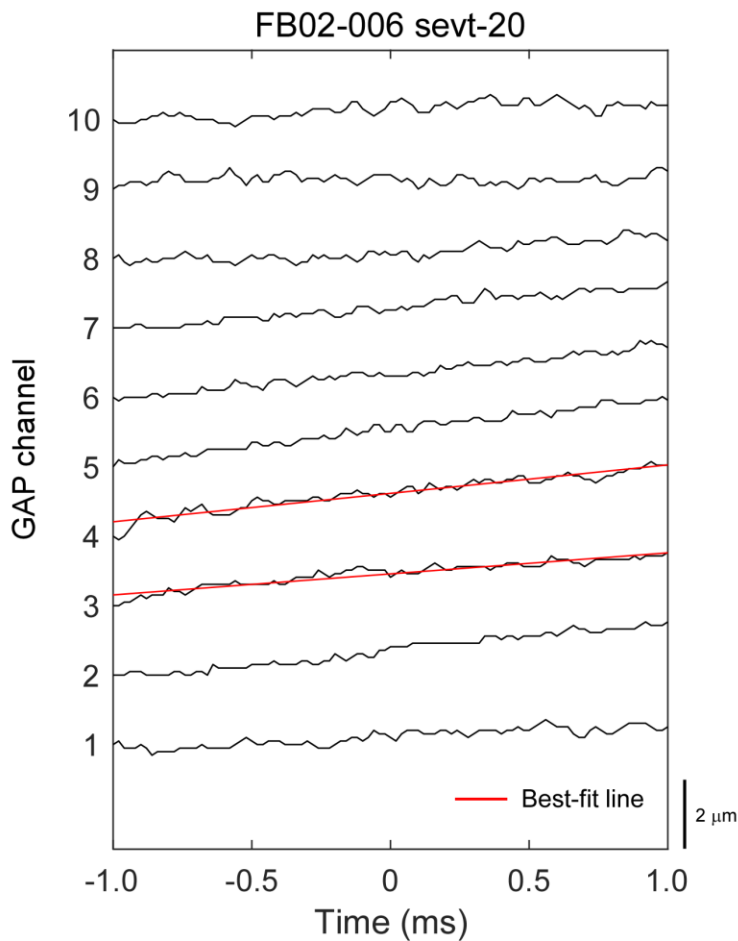

659

660   **Figure A3.** An example of estimation of local slip rate related to a seismic event. This panel
661   shows the local slip data for 1 ms before and after the occurrence of a seismic event sevt-20 in
662   FB02-006. The local slip rate at the same site and time as the seismic event is estimated from
663   linear interpolation of the best-fit trends for the slip data at the neighboring slip sensors as shown
664   by red lines.

665   **Appendix B: Seismic activity**

666   B.1 Hypocenter and size of seismic events

667   Based on the seismic record, we determined the origin time and hypocenter location of

668 the foreshocks. We first specified the time when a foreshock occurred by referring to local peaks

669 of the sum of squared AS amplitude (Figure B1b). We next picked up the time-window for each

670 foreshock as shown in Figure 3, and then picked the arrival times of seismic waves. For the

671 picking, we did not use AS waveform but used SGT waveform, because AS array is sparse

672 relative to SGT array and the arrival of S wave was clearer for the record of SGT as shown in

673 Figure 3. After picking the arrival time of S wave at each station, we conducted a grid search to

674 determine the origin time and the location of hypocenter. We searched for the optimum

675 parameters including the wave velocity (V), so that the following L^2 norm becomes minimum:

676       $$L^2 = \sum_{i=1}^{N} \left(t_i - t_0 - \frac{D_i}{V} \right)^2 \qquad \text{(B.1)},$$

677 where N is the number of SGT stations, t_i is the arrival time at i-th SGT station, t_0 is the origin

678 time, and D_i is the distance between the hypocenter (x_0, y_0, z_0) and the location of i-th SGT

679 station (x_i, y_i, z_i) as follow:

680       $$D_i = \sqrt{(x_i - x_0)^2 + (y_i - y_0)^2 + (z_i - z_0)^2} \qquad \text{(B.2)}.$$

681   In this search, we assumed that the foreshocks occurred on the fault surface (i.e. z_0=0).

682 After locating the hypocenter, we estimated the magnitude of the foreshock based on the

683 amplitudes of AS. Unfortunately, we could not calibrate the response of AS sensor. Instead, we

684 estimated a laboratory-specific magnitude M_{Lab} following Zang et al. (1998):

685       $$M_{Lab} = \log_{10} A \qquad \text{(B.3), and}$$

686       $$A = \sqrt{\frac{1}{K} \sum_{i=1}^{K} \left(\frac{r_i}{10} A_{i_{max}} \right)^2} \qquad \text{(B.4)},$$

687 where K is the number of AS stations, r_i is the distance between the hypocenter and i-th AS

688 station in mm, and $A_{i_{max}}$ is the maximum amplitude of seismic wave at i-th AS station in volt.

689 $A_{i_{max}}$ is mainly derived from S wave. The estimated hypocenters and M_{Lab} values of foreshocks
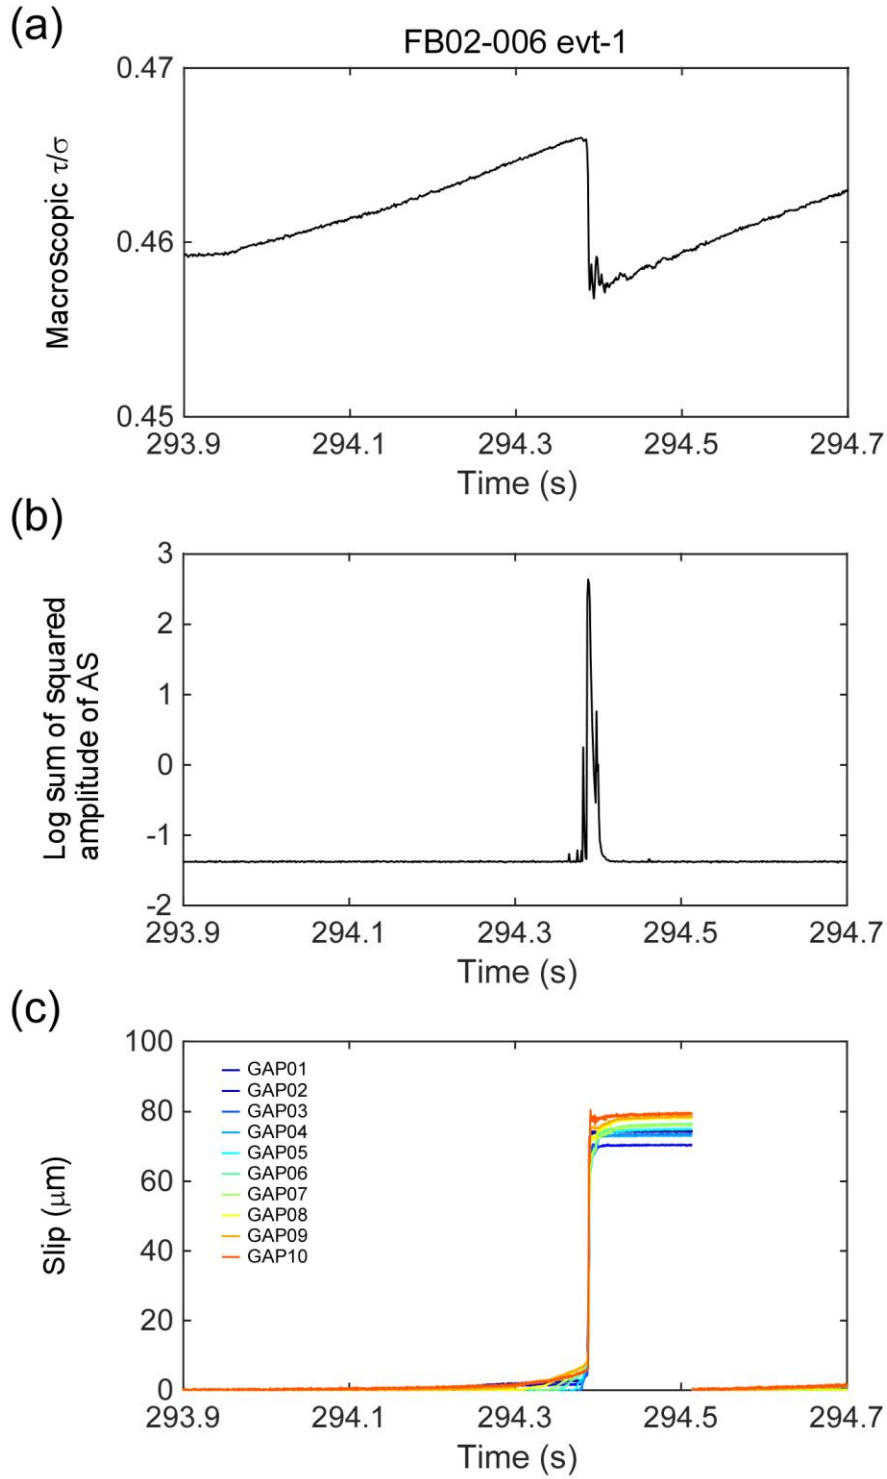

690 are shown in Figure 6.

691 **Figure B1.** Close-up view of (a) Macroscopic τ/σ, (b) logarithmic sum of squared amplitude of
692 AS output, and (c) the amount of slip for experiment FB02-006 evt-1.

693   B.2 Matched filter technique

694   Matched filter technique (MFT) is an effective means for detecting a seismic event whose

695   hypocenter and focal mechanism are close to those of a template event. MFT scans a continuous

696   seismic record and detects similar waveforms to the template waveforms. This technique has

697   been widely used for detecting various seismic events such as low-frequency earthquakes (Shelly

698   et al., 2007), aftershocks (Peng & Zhao, 2009), and foreshocks (Kato et al., 2012).

699   For applying MFT, we first need to determine template foreshocks. We searched for

700   groups producing more than five foreshocks within 15 mm of relative hypocentral distances, and

701   then defined the foreshock with the largest M_{Lab} (whose signal-to-noise ratio should be high) in

702   each group as the template foreshock. We excluded one template foreshock whose signals

703   saturated in many AS stations. As a result, we found four template foreshocks in total and named

704   them template A, B, C, and D. The hypocenters of the template foreshocks are shown in Figure

705   6. As the template waveforms for scanning, we used a 0.25-ms-long time window beginning 0.05

706   ms prior to the estimated S wave arrival time. The waveforms of template foreshock D are

707   displayed in Figure B2 as an example. By using the four sets of the template waveforms, we

708   scanned throughout the continuous seismic records of four experiments. We computed

709   correlation coefficients between the template waveforms and those in the seismic records with

710   shifting one data point (10^{-7} s). The calculated correlation coefficients were averaged over all

711   station channels at each step. We set two thresholds to detect a repeating foreshock: (1) the

712   averaged correlation coefficient normalized by standard deviation is more than 8, and (2) the

713   averaged correlation coefficient is more than 0.3. As a result, we detected 3, 5, 6, and 9 repeating

714   foreshocks for template A, B, C, and D, and then named them Group A, B, C, and D,

715   respectively. An example for the waveforms of a detected repeating foreshock is shown in Figure

716   B2. The cross symbols in Figures 2b, 2e, 2h, and 2k represent the occurrence times of the

717   repeating foreshocks in each group. The results suggest that the repeating foreshocks did not

718   recur during a single stick-slip cycle but were activated before different main stick-slip events.

719   The detailed information of the repeating foreshocks is shown in Table B1.
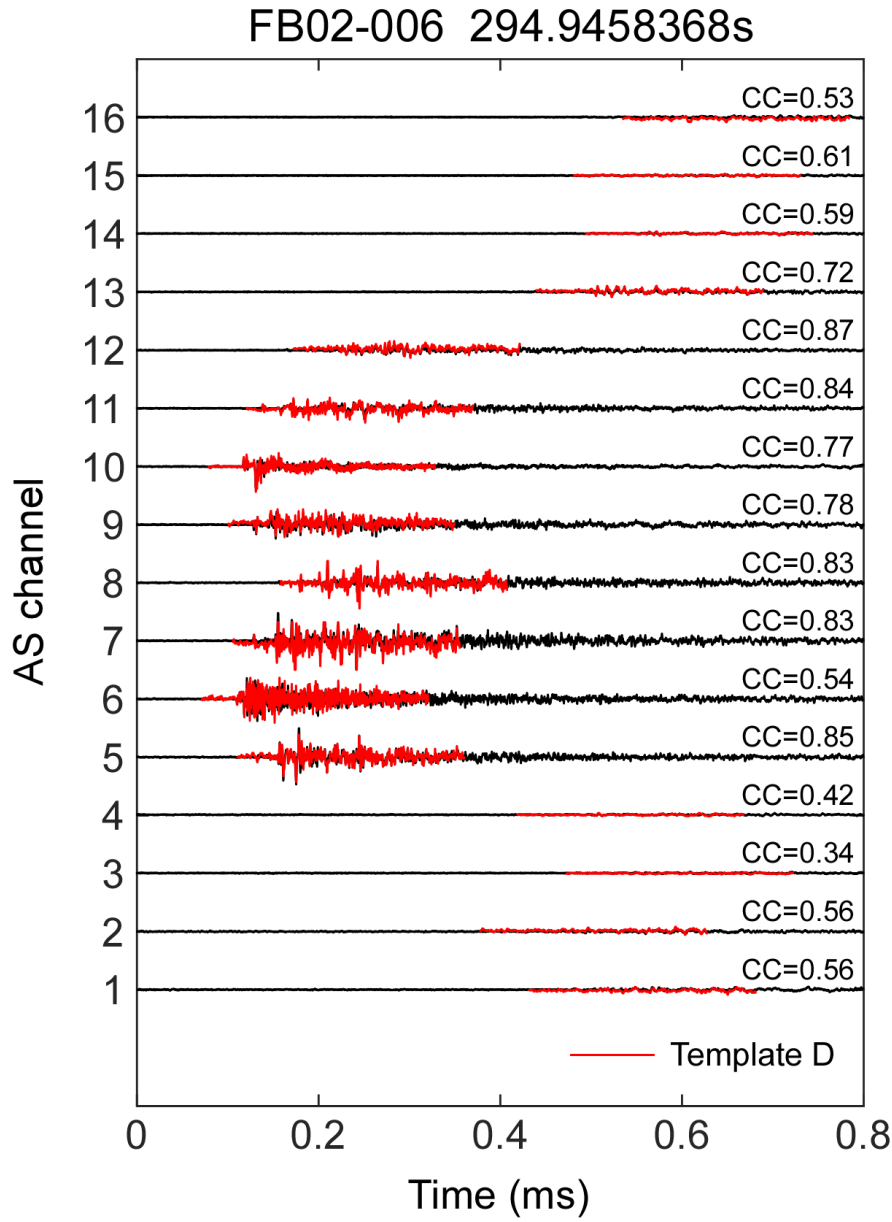

Figure B2. An example of a detected repeating foreshock event by the matched filter technique. Waveforms for the template foreshock D are overlaid with red lines on those for the detected repeating foreshock. Amplitudes are normalized by the maximum amplitude in all channels.

725 **Table B1** *Properties of repeating foreshocks*

727 **Distance from southern edge of the upper specimen.

728 ***Proportion of the variance for positive correlation of waveforms between template foreshock
729 and repeating one to the total variance.

730

731   B.3 Relative magnitude of repeating foreshocks

732   For simple but robust estimation of the relative magnitude of repeating foreshocks, we

733   directly compared the amplitudes of the observed waveforms in the time domain. For this

734   comparison, we used the same data window as MFT, that is, the 0.25-ms-long time window

735   beginning 0.05 ms prior to the *S* wave arrival time. According to a previous study (McLaskey et

736   al., 2014) that used the same acoustic sensor (V103) as the current study, the sensor output is

737   almost proportional to ground displacement in the frequency band of 30 kHz-1 MHz. Therefore,

738   we band-pass filtered the waveforms of the template and the repeating foreshocks with that

739   frequency band before the comparison. Figure B3 shows the AS output for the repeating

740   foreshocks against that for the template foreshock at each AS station. Since all groups of the

741   repeating foreshocks were distributed around the central fault area (Figure 6), we only used the

742   waveforms recorded by the central eight AS stations (AS05 to AS12). All data points recorded at

743   the eight stations are stacked in each panel and used for the following analysis. The best-fit trend

744   is equal to the amplitude ratio of the repeating foreshocks to the template one. This trend R

745   should be roughly proportional to the ratio of the seismic moment of the repeating foreshock to

746   that of the template foreshock. It should be noted that effects of geometric attenuation and

747   instrumental responses are canceled out by taking the ratio. Considering the relation $M_w' - M_w'' =$

748    $\frac{2}{3}\log_{10}\left(\frac{M_0'}{M_0''}\right)$, where M_w' and M_w'' are arbitrary moment magnitudes and M_0' and M_0'' are associated

749   seismic moments, respectively, from the definition of Eq. (3), common logarithm of R should

750   scale with a relative magnitude of the repeating foreshock to the magnitude of template

751   foreshock. We name it M_r and show the estimated values in Table B1. For the estimation of the

752   trend, we applied a principal component analysis with two variables. Proportion of the variance

753   for the first principal component (positive correlation of waveforms between the template

754   foreshock and the repeating one) to the total variance, which indicates how well the distribution

755   is explained by the associated relation, is high enough as shown in Table B1.
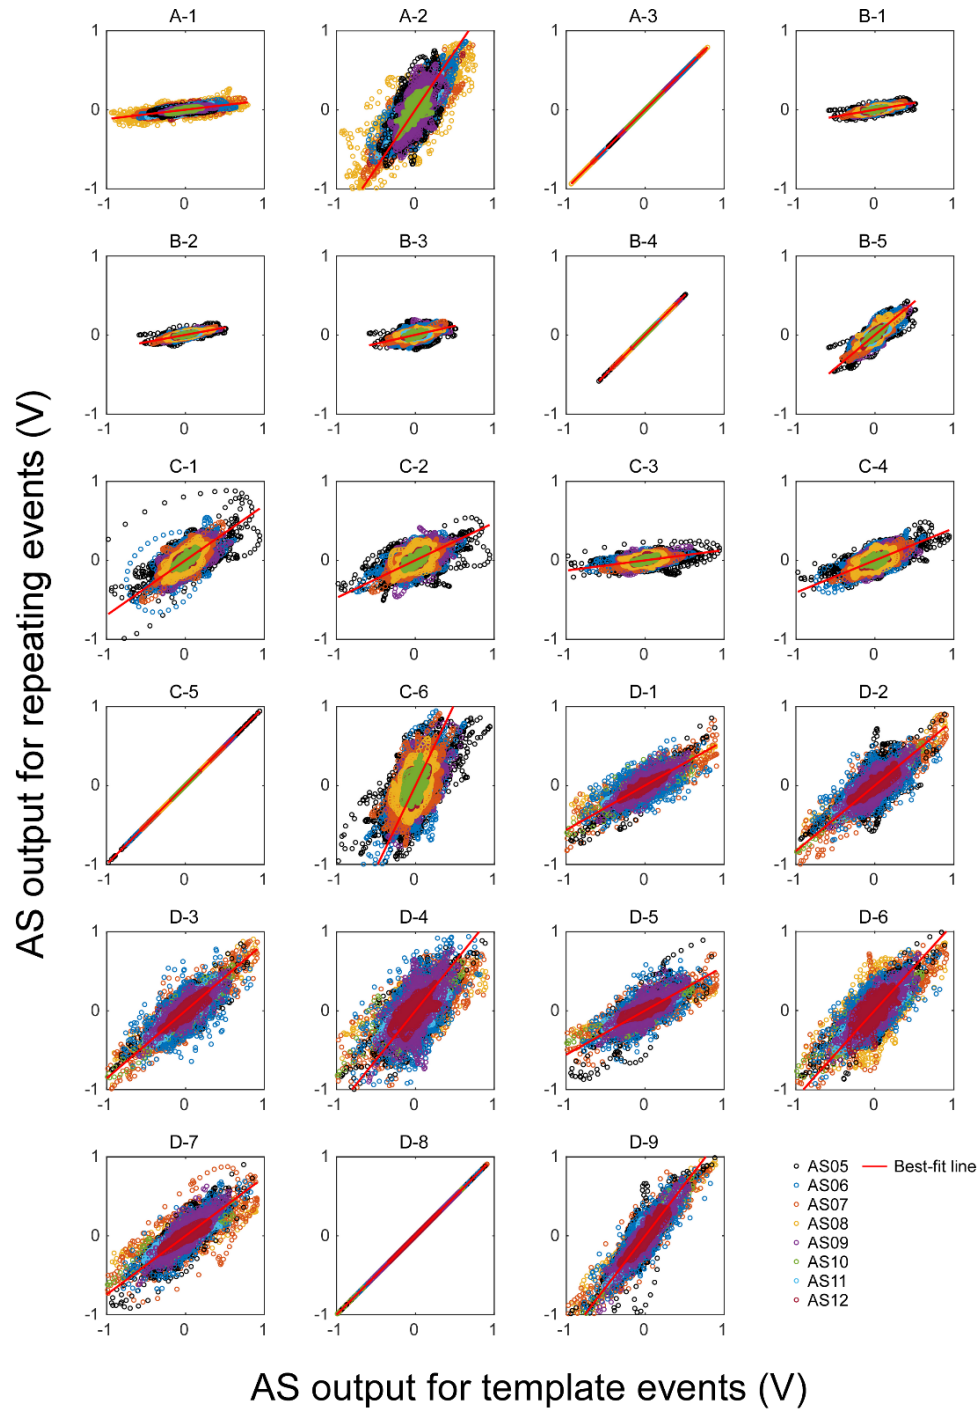

Figure B3. Band-pass filtered outputs of acoustic sensors (AS) for matched foreshocks against those for the template foreshocks. The records obtained at AS05 to AS12 are displayed and used for the estimation of relative waveform amplitude. Red linear line shows the best-fit trend estimated with the principal component analysis. The associated event ID is displayed above each panel. Note that A-3, B-4, C-5, and D-8 are the template foreshocks for each group.
