15 **Key Points**

16 - A deep learning-based data assimilation method, named PEDL, is proposed to
17 characterize fractured media with highly non-Gaussian features.

18 - PEDL outperforms three popular data assimilation methods based on deep learning or the
19 Kalman formula.

20 - Sensitivity analyses confirm PEDL's validity and adaptability across various ensemble
21 sizes and DL model architectures.

Abstract

In various research fields such as hydrogeology, environmental science and energy engineering, geological formations with fractures are frequently encountered. Accurately characterizing these fractured media is of paramount importance when it comes to tasks that demand precise predictions of liquid flow and the transport of solute and energy within them. Since directly measuring fractured media poses inherent challenges, data assimilation (DA) techniques are typically employed to derive inverse estimates of media properties using observed state variables like hydraulic head, concentration, and temperature. Nonetheless, the considerable difficulties arising from the strong heterogeneity and non-Gaussian nature of fractured media have diminished the effectiveness of existing DA methods. In this study, we formulate a novel DA approach known as PEDL (parameter estimator with deep learning) that harnesses the capabilities of DL to capture nonlinear relationships and extract non-Gaussian features. To evaluate PEDL's performance, we conduct two numerical case studies with increasing complexity. Our results unequivocally demonstrate that PEDL outperforms three popular DA methods: ensemble smoother with multiple DA (ESMDA), iterative local updating ES (ILUES), and ES with DL-based update (ESDL). Sensitivity analyses confirm PEDL's validity and adaptability across various ensemble sizes and DL model architectures. Moreover, even in scenarios where structural difference exists between the accurate reference model and the simplified forecast model, PEDL adeptly identifies the primary characteristics of fracture networks.

1 Introduction

Fractures are narrow openings or mechanical discontinuities in geological formations, typically found in rocks, soils, and aquifers. The significance of fractures lies in their pivotal role across numerous processes: they offer preferential pathways for the rapid transport of liquids, and act as reservoirs for fluid storage and release (Viswanathan et al., 2022). Despite their relatively minor presence within the subsurface media, fractures hold importance in diverse fields, including Karst aquifer management (S Li et al., 2020), geothermal energy production (Guo et al., 2022), hydrocarbon extraction (F Zhang & Emami-Meybodi, 2022), geological sequestration of CO_2 (Luo et al., 2022), and nuclear waste disposal (Saceanu et al., 2022). Nonetheless, the complexity

51   of fractured media is deeply ingrained in the coexistence of fractures with varying sizes,

52   orientations, and apertures. This complexity engenders significant heterogeneity, anisotropy, and

53   discontinuity in the hydraulic characteristics of fractured media, ultimately giving rise to

54   elevated levels of uncertainty in flow and transport predictions (Neuman, 2005). For achieving

55   trustworthy process comprehension and simulation outcomes, it is imperative to effectively

56   characterize the attributes of fractured media and reasonably quantify the associated uncertainty

57   (Hyman, 2020; Klepikova et al., 2020).

58   Given the inherently opaque and complex nature of fractured media, the direct observation of

59   fractures poses a formidable challenge. Although X-ray computed tomography can be employed

60   to study the structure of fracture in specific scenarios, it is subject to limitations related to

61   method resolution and sample size (C Jiang et al., 2019; Hao Wu et al., 2019). An alternative

62   approach to characterizing fractured media involves the use of numerical models that explicitly

63   represent fracture networks, particularly the major ones (Berre et al., 2019). These models, often

64   referred to as discrete fracture models (DFMs), encompass a range of methodologies, including

65   channel networks (Hyman, 2020), discrete fracture networks (Cacas et al., 1990), discrete

66   fracture-matrix models (Koohbor et al., 2020), and embedded discrete fracture-matrix (EDFM)

67   models (J Jiang & Younis, 2017). To characterize the inherent structural complexity and scale

68   disparities within fracture networks, it is often imperative to employ fine spatial resolutions.

69   Nevertheless, this approach can make simulations prone to griding failures, result in high

70   computational expenses, and, as a consequence, prove infeasible for extensive, large-scale

71   problems (Viswanathan et al., 2022). A simpler yet less precise approach for representing

72   fractures involves utilizing continuum models, where effective parameter values of the matrix

73   are employed. These models include the stochastic continuum (SC) model (Tsang et al., 1996)

74   and the dual-permeability model (Presho et al., 2011). While these models may not provide the

75   same level of accuracy as DFMs, they are known for their ease of implementation and cost-

76   effectiveness in practical applications (National Academies of Sciences, 2020).

77   In the aforementioned models, a substantial number of parameters are indispensable for

78   representing complex fractures. However, these parameters remain predominantly unknown,

79   introducing considerable uncertainty when simulating flow and transport processes happening

80   within the fractured media. To confront this challenge, researchers have underscored the growing

81   importance of incorporating diverse data types, encompassing hydraulic, geophysical, and hydro-

82　chemical measurement data, through the implementation of data assimilation (DA) techniques

83　(Elahi & Jafarpour, 2018; Y Li et al., 2016; Miskimins, 2009; Ping & Zhang, 2013; Hui Wu et al.,

84　2021). DA is devoted to seamlessly integrating theoretical knowledge, often represented as

85　numerical models, with observational data to achieve optimized estimations of system states,

86　parameters, and initial/boundary conditions. It has found extensive applications across various

87　research domains of geosciences (Carrassi et al., 2018; Fletcher, 2022), and can serve as a

88　valuable tool for enhancing our understanding of fractures and their properties.

89　When characterizing fractured media, the prevailing DA approach in use is ensemble Kalman

90　filter (EnKF) (Evensen, 2009) and its iterative variations, such as ESMDA (Emerick & Reynolds,

91　2013) and EnRML (Gu & Oliver, 2007). For instance, Vogt et al. (2012) employed EnKF to

92　assimilate tracer data, aiming to estimate equivalent permeability field of discrete fracture

93　networks at an enhanced geothermal system reservoir. However, their predictions display a

94　noticeable degree of uncertainty, which could be attributed to the inherent constraints of EnKF

95　and its variants in handling non-Gaussian distributions. To tackle this challenge, a viable strategy

96　involves transforming non-Gaussian distributed variables into Gaussian ones using various

97　techniques. For example, Hui Wu et al. (2021) applied principal component analysis, Chen et al.

98　(2023) used deep generative model, Ping & Zhang (2013) utilized level set function, and Lu &

99　Zhang (2015) employed Hough transformation, respectively, to reparameterize complex

100　fractured media with Gaussian random variables. These Gaussian distributed variables can be

101　effectively updated using EnKF or its variants, and then transformed back to non-Gaussian

102　distributed fracture parameters to make predictions with dynamic models. Nevertheless, it's

103　important to note that the reparameterization and updating processes may lead to the loss of

104　some basic features and continuity of fractures (Yao et al., 2018). Another strategy for

105　addressing the non-Gaussianity issue entails adopting more theoretically robust DA methods,

106　such as Markov chain Monte Carlo (MCMC) (Vrugt, 2016) and particle filter (PF) (Djuric et al.,

107　2003). For example, Blaheta et al. (2020) and Xue et al. (2020) respectively employed MCMC

108　and PF for the characterization of fractured media in subsurface applications. Nevertheless, the

109　computational costs associated with MCMC and PF can become prohibitive when dealing with

110　high-dimensional inverse problems. Even with the incorporation of lower-fidelity or surrogate

111　models to improve efficiency in the two studies, the practical application of MCMC and PF

112　techniques remains a formidable challenge. In addition to the challenge posed by non-

113   Gaussianity, another prevalent and complex issue in the realm of DA for subsurface

114   characterization is equifinality, which refers to the scenario where various model structures and

115   parameter combinations can yield acceptable reproductions of observed system behaviors (Beven

116   & Freer, 2001). From the Bayesian perspective, equifinality means that the parameter

117   distribution is multi-modal in ensemble sense. Several studies have tried to handle multi-modal

118   distributions in DA by conceptualizing them as a mixture of Gaussian distributions, with each of

119   these distributions being updated individually (Elsheikh et al., 2013; Sun et al., 2009; J Zhang et

120   al., 2018). Among them, the iterative local updating ensemble smoother (ILUES) proposed by J

121   Zhang et al. (2018) has been used as the basic DA method in various subsurface characterization

122   problems.

123   Over the past decade, deep learning (DL) has gained substantial attention within the field of

124   hydrology and water resources (Shen, 2018). DL's prowess in unveiling complex nonlinear

125   relationships and intricate patterns from data has endowed it with formidable analytical

126   capabilities. Moreover, the strong alignment between DL and DA in terms of statistical

127   principles and methodologies has been well investigated and recognized (Abarbanel et al., 2018;

128   Berry & Harlim, 2017). In an effort to tackle the challenges posed by high-dimensionality and

129   non-Gaussianity in DA problems, J Zhang et al. (2020) put forth an innovative approach. They

130   proposed the utilization of DL to establish a nonlinear updating scheme that supplants the

131   conventional Kalman updating in EnKF and its variants. Their findings showcased the efficacy

132   of this DL-based DA method, known as ESDL, in effectively characterizing high-dimensional,

133   non-Gaussian parameter fields. Due to its capability to address complex DA problems, ESDL

134   and its variants have found applications in numerous subsurface characterization scenarios

135   (Godoy et al., 2022; Man et al., 2022; Wang & Yan, 2022; Xiao et al., 2023; J Zhang et al.,

136   2023).

137   In the present study, we adopt the ESDL method for the first time to characterize fractured media.

138   While ESDL exhibits improved performance compared to Kalman-based DA methods like

139   ESMDA and ILUES, it is not without its limitations, as will be demonstrated later in this work.

140   The fracture networks inferred by ESDL exhibit some irregularities, possibly due to the updating

141   process from the innovation vector (i.e., the difference between observations and model

142   predictions) to the update vector (i.e., the difference between posterior and prior parameters).

143   Based on this finding, we improve ESDL by introducing a new updating rule. This new DA

144   method, named parameter estimator with DL (PEDL), establishes a direct update from the multi-

145   sourced observation vector to the posterior parameter vector. To validate PEDL's effectiveness,

146   we compare its performance with several existing DA methods, including ESMDA, ILUES, and

147   ESDL, in a groundwater flow problem within fractured media. As will be demonstrated later,

148   PEDL outperforms the other three DA methods significantly in characterizing the fractured

149   media.

150   The rest of this paper is structured as follows. In Section 2, we present the implementation details

151   of PEDL, along with three well-known DA methods for comparative analysis, namely ESMDA,

152   ILUES, and ESDL. Section 3 features two illustrative cases aimed at evaluating the performance

153   of PEDL in the context of DA within fractured media. Here, we consider two scenarios with and

154   without considering the model structural error, respectively. Finally, in Section 4, we draw

155   conclusions and engage in a discussion about the applicability of PEDL in a broader perspective.

2 Methodology

157   Here, we assume that the process of concern (e.g., groundwater flow within a fractured aquifer)

158   is simulated by a numerical model $\mathcal{F}(\mathbf{m})$. The true parameters $\mathbf{m}^*$ describing the media

159   properties (e.g., permeability) are unknown and can be inferred from noisy measurement data

$$\tilde{\mathbf{d}} = \mathcal{F}(\mathbf{m}^*) + \boldsymbol{\varepsilon}, \tag{1}$$

160   where $\boldsymbol{\varepsilon} \sim \mathcal{N}(\mathbf{0}, \mathbf{C}_{\mathrm{D}})$ represent the error terms. Based on the Bayesian theory, our updated

161   understanding about the parameters can be expressed as the posterior distribution

$$p(\mathbf{m}|\tilde{\mathbf{d}}) = \frac{p(\mathbf{m})p(\tilde{\mathbf{d}}|\mathbf{m})}{p(\tilde{\mathbf{d}})}, \tag{2}$$

162   where $p(\mathbf{m})$ is the prior distribution of $\mathbf{m}$, $p(\tilde{\mathbf{d}}|\mathbf{m})$ demotes the likelihood function, and $p(\tilde{\mathbf{d}}) =$

163    $\int p(\tilde{\mathbf{d}}|\mathbf{m})p(\mathbf{m})d\mathbf{m}$ signifies the evidence, a normalization constant.

164   For complex problems, analytical form of $p(\mathbf{m}|\tilde{\mathbf{d}})$ is not available, and Monte Carlo methods

165   can be employed to approximate the posterior. According to the background knowledge of $\mathbf{m}$, N_{e}

166   random samples can be drawn to form the prior ensemble, $\mathbf{M}^0 = \{\mathbf{m}_i^0 | i = 1, \dots, N_{\mathrm{e}}\}$. With the

167   numerical model, the corresponding model outputs can be calculated, i.e., $\mathbf{D}^0 = \{\mathbf{d}_i^0 =$

168 $\mathcal{F}(\mathbf{m}_i^0)|i = 1, ..., N_e\}$. Below we will introduce how to update $\mathbf{M}^0$ from $\tilde{\mathbf{d}}$ with various DA

169 methods, including ESMDA, ILUES, ESDL and PEDL.

2.1 Ensemble Smoother with Multiple Data Assimilation: ESMDA

171 Using the Kalman formula, we can update each sample in $\mathbf{M}^0$ as follows:

$$\mathbf{m}_i^1 = \mathbf{m}_i^0 + \mathbf{C}_{MD}^0(\mathbf{C}_{DD}^0 + \mathbf{C}_D)^{-1}(\tilde{\mathbf{d}} + \boldsymbol{\varepsilon}_i - \mathbf{d}_i^0), \tag{3}$$

172 where $\mathbf{M}^1 = \{\mathbf{m}_i^1|i = 1, ..., N_e\}$ is the updated ensemble representing our posterior

173 understanding about the model parameters, $\mathbf{C}_{MD}^0$ is the cross-covariance between $\mathbf{M}^0$ and $\mathbf{D}^0$,

174 $\mathbf{C}_{DD}^0$ is the auto-covariance of $\mathbf{D}^0$, and $\boldsymbol{\varepsilon}_i$ is a random realization of measurement errors,

175 respectively. For highly nonlinear problems, iterative application of the Kalman updating of

176 equation (3) can be adopted:

$$\mathbf{m}_i^t = \mathbf{m}_i^{t-1} + \mathbf{C}_{MD}^{t-1}(\mathbf{C}_{DD}^{t-1} + \alpha^t\mathbf{C}_D)^{-1}\left(\tilde{\mathbf{d}} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_i - \mathbf{d}_i^{t-1}\right), \tag{4}$$

177 where $t = 1, ..., N_{iter}$, α^t is the inflation factor that satisfies $\sum_{t=1}^{N_{iter}} 1/\alpha^t = 1$, and N_{iter} is the

178 iteration number. Finally, we use $\mathbf{M}^{N_{iter}} = \left\{\mathbf{m}_i^{N_{iter}}|i = 1, ..., N_e\right\}$ to approximate the posterior

179 distribution of $\mathbf{m}$. For the theory and implementation details of ESMDA, one can refer to

180 (Emerick & Reynolds, 2013).

2.2 Iterative Local Updating Ensemble Smoother: ILUES

182 When the posterior distribution of parameters $\mathbf{m}$ exhibits multiple modes, signifying that distinct

183 parameter sets can equally reproduce the measurement data, the straightforward application of

184 ESMDA may lead to biased results. This phenomenon, known as the equifinality issue, is a

185 common challenge encountered in DA for complex systems, particularly when the available

186 information contained in the measurement data is insufficient. To reasonably represent the multi-

187 modal posterior distribution, J Zhang et al. (2018) proposed to identify and update the local

188 ensemble of each sample $\mathbf{m}_i^{t-1}$ in $\mathbf{M}^{t-1}$ independently at iteration $t = 1, ..., N_{iter}$. The local

189 ensemble of $\mathbf{m}_i^{t-1}$ is based on the following measure:

$$\mathcal{J}(\mathbf{m}) = \mathcal{J}_1(\mathbf{m})/\mathcal{J}_1^{max} + \mathcal{J}_2(\mathbf{m})/\mathcal{J}_2^{max}, \tag{5}$$

190   where $\mathcal{J}_1(\mathbf{m}) = (\mathbf{m} - \mathbf{m}_i^{t-1})\mathbf{C}_{\mathrm{MM}}^{-1}(\mathbf{m} - \mathbf{m}_i^{t-1})^{\mathrm{T}}$, $\mathcal{J}_2(\mathbf{m}) = (\mathcal{F}(\mathbf{m}) - \tilde{\mathbf{d}})\mathbf{C}_{\mathrm{D}}^{-1}(\mathcal{F}(\mathbf{m}) - \tilde{\mathbf{d}})^{\mathrm{T}}$, $\mathbf{C}_{\mathrm{MM}}$

191   is the auto-covariance of model parameters, $\mathcal{J}_1^{\max}$ is the maximum value of $\mathcal{J}_1$, and $\mathcal{J}_2^{\max}$ is the

192   maximum value of $\mathcal{J}_2$, respectively. The local ensemble of $\mathbf{m}_i^{t-1}$ is the $N_{\mathrm{L}} = \beta N_{\mathrm{e}}$ $(0 < \beta \leq 1)$

193   samples in $\mathbf{M}^{t-1}$ with the smallest $\mathcal{J}$ values, i.e., $\mathbf{M}_i^{t-1} = \{\mathbf{m}_{i,j}^{t-1} | j = 1, \dots, N_{\mathrm{L}}\}$. Each sample in

194   $\mathbf{M}_i^{t-1}$ can be updated as:

$$\mathbf{m}_{i,j}^t = \mathbf{m}_{i,j}^{t-1} + \mathbf{C}_{i,\mathrm{MD}}^{t-1}(\mathbf{C}_{i,\mathrm{DD}}^{t-1} + \alpha^t \mathbf{C}_{\mathrm{D}})^{-1}(\tilde{\mathbf{d}} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_j - \mathbf{d}_{i,j}^{t-1}), \tag{6}$$

195   where $\mathbf{C}_{i,\mathrm{MD}}^{t-1}$ is the cross-covariance between $\mathbf{M}_i^{t-1}$ and $\mathbf{D}_i^{t-1} = \{\mathbf{d}_{i,j}^{t-1} = \mathcal{F}(\mathbf{m}_{i,j}^{t-1}) | j = 1, \dots, N_{\mathrm{L}}\}$,

196   $\mathbf{C}_{i,\mathrm{DD}}^{t-1}$ is the auto-covariance of $\mathbf{D}_i^{t-1}$, respectively. The updated sample of $\mathbf{m}_i^{t-1}$, i.e., $\mathbf{m}_i^t$, can be

197   randomly drawn from the updated local ensemble, $\mathbf{M}_i^t = \{\mathbf{m}_{i,j}^t | j = 1, \dots, N_{\mathrm{L}}\}$. Finally, we use

198   $\mathbf{M}^{N_{\mathrm{iter}}} = \{\mathbf{m}_i^{N_{\mathrm{iter}}} | i = 1, \dots, N_{\mathrm{e}}\}$ to approximate the posterior distribution of $\mathbf{m}$ with possible

199   multi-modes. More details about ILUES can be found in (J Zhang et al., 2018).

2.3 Ensemble Smoother with Deep Learning-based Update: ESDL

201   Essentially, the Kalman update used in ESMDA and ILUES builds a linear relationship between

202   the innovation vector, $\Delta\mathbf{d}_i^t = \tilde{\mathbf{d}} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_i - \mathbf{d}_i^{t-1}$, and the update vector, $\Delta\mathbf{m}_i^t = \mathbf{m}_i^t - \mathbf{m}_i^{t-1}$:

$$\Delta\mathbf{m}_i^t = \mathbf{K}^t \Delta\mathbf{d}_i^t, \tag{7}$$

203   where $\mathbf{K}^t = \mathbf{C}_{\mathrm{MD}}^{t-1}(\mathbf{C}_{\mathrm{DD}}^{t-1} + \alpha^t \mathbf{C}_{\mathrm{D}})^{-1}$ is the so-called Kalman gain matrix. As the above calculation

204   is only based on the mean and covariance, the Kalman-based DA is subjected to the Gaussian

205   assumption. Inspired by the universal approximation and pattern recognition abilities of DL, J

206   Zhang et al. (2020) proposed to supplant the Kalman-based update in EnKF and its variants with

207   a DL-based counterpart:

$$\Delta\mathbf{m}_i^t = \mathcal{G}_{\mathrm{DL}}^t(\Delta\mathbf{d}_i^t), \tag{8}$$

208   where $\mathcal{G}_{\mathrm{DL}}^t(\cdot)$ is a nonlinear mapping from the innovation vector to the update vector based on

209   DL. The effective training of $\mathcal{G}_{\mathrm{DL}}^t(\cdot)$ can be facilitated by the vast amount of data directly

210   generated from $\mathbf{M}^{t-1}$ and $\mathbf{D}^{t-1}$, i.e., $\mathbf{X}^t = \{\mathbf{x}_{\mathrm{input}} = \mathbf{d}_i^{t-1} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_{ij} - \mathbf{d}_j^{t-1}, \mathbf{x}_{\mathrm{target}} = \mathbf{m}_i^{t-1} -$

211   $\mathbf{m}_j^{t-1} | i = 1, \dots, N_{\mathrm{e}} - 1, i < j \leq N_{\mathrm{e}}\}$. Here, we treat $\{\mathbf{m}_i^{t-1}, \mathbf{d}_i^{t-1}\}$ as the synthetic truth and can

212   produce $N_e - 1$ pairs of innovation and update vectors from the rest ensemble members. In total,

213   there are $C_{N_e}^2 = N_e(N_e - 1)/2$ training samples in $\mathbf{X}^t$. Results shown that ESDL can better solve

214   DA problems involving high-dimensional and non-Gaussian distributed parameters than its

215   Kalman-based counterpart (J Zhang et al., 2020).

216   **2.4 Parameter Estimator with Deep Learning: PEDL**

217   In ESDL, what $\mathcal{G}_{DL}^t(\cdot)$ tries to capture is the relationship between the increment in parameters,

218   i.e., $\Delta\mathbf{m}_i^t$, and the displacement in model responses, i.e., $\Delta\mathbf{d}_i^t$, and the updated parameters are

219   obtained as:

$$\mathbf{m}_i^t = \mathbf{m}_i^{t-1} + \Delta\mathbf{m}_i^t. \tag{9}$$

220   In the context of fractured media, $\mathbf{m}$ describe the spatial distribution of hydraulic properties,

221   encompassing distinct parameter values (high values for the fractures, and low values for the

222   matrix). During the training of $\mathcal{G}_{DL}^t(\cdot)$, the information about the starting point of $\Delta\mathbf{m}_i^t$, i.e., $\mathbf{m}_i^{t-1}$,

223   is not considered. Consequently, there is a potential mismatch between the regions with high and

224   low values in $\mathbf{m}_i^{t-1}$ and $\Delta\mathbf{m}_i^t$, as the inferences made by $\mathcal{G}_{DL}^t(\cdot)$ are not flawless. When $\mathbf{m}_i^{t-1}$ and

225    $\Delta\mathbf{m}_i^t$ are added up, this imperfection can lead to irregularities in the fracture networks inferred by

226   ESDL, as illustrated in Figure 5 (Section 3.1.2), highlighting this limitation.

227   To tackle this concern, here we modify ESDL by shifting the target of DL from the update vector

228    $\Delta\mathbf{m}_i^t$ to the target parameter set $\mathbf{m}_i^t$ directly:

$$\mathbf{m}_i^t = \mathcal{G}_{DL}^t\left(\mathbf{m}_i^{t-1}, \tilde{\mathbf{d}} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_i, \mathbf{d}_i^{t-1}\right). \tag{10}$$

229   To distinguish it from ESDL, we have named the new method PEDL (parameter estimator with

230   DL). PEDL avoids the use of the difference vectors in ESMDA, ILUES and ESDL. Thus, the

231   mismatches between $\mathbf{m}_i^{t-1}$ and $\Delta\mathbf{m}_i^t$ in ESDL will not affect the results anymore. However, the

232   implementation of PEDL as described in equation (10) is ambiguous. After comprehensive

233   testing, we suggest to adopt a simplified form of equation (10), i.e.,

$$\mathbf{m}_i^t = \mathcal{G}_{DL}^t\left(\tilde{\mathbf{d}} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_i\right). \tag{11}$$

234 Here, the training data for the DL model are $\{\mathbf{x}_{\text{input}} = \mathbf{d}_i^{t-1} + \sqrt{\alpha^t}\boldsymbol{\varepsilon}_i, \mathbf{x}_{\text{target}} = \mathbf{m}_i^{t-1} | i =$

235 $1, \ldots, N_e\}$. As will be demonstrated in latter part of this work, this new method is very easy to

236 implement, and can obtain more reliable estimations of fractured media than the other three DA

237 methods, i.e., ESMDA, ILUES, and ESDL.

3 Illustrative Case Studies

3.1 Case 1: Data Assimilation without Considering Model Structural Error

240 3.1.1 Model Settings

241 In this section, we set up a case study involving transient groundwater flow in a two-dimensional

242 (2-D) fractured aquifer to evaluate the performance of PEDL. We employ the SC model (Tsang

243 et al., 1996) as both the reference model providing the ground truth and the forecast model used

244 in DA. In this context, we can disregard the error stemming from model structures, allowing us

245 to directly compare the performance of PEDL with ESMDA, ILUES, and ESDL.

246 The flow domain is 205[L]×205[L] (in unit of length) and is discretized into 41×41 grids with a

247 uniform spacing of 5[L] in the numerical model. All four lateral boundaries are impermeable.

248 The domain predominantly consists of a matrix with permeability of $k_{\text{m}} = 10^{-13}[\text{L}^2]$, but there

249 exist regions with considerably higher permeability values due to the presence of fractures.

250 Figure 1 illustrates the reference distribution of the fractured zones, with isotropic permeability

251 of $k_{\text{f}} = 90k_{\text{m}}$. The simulation period spans $T_{\text{s}} = 86400[\text{T}]$ (in unit of time) and is evenly

252 divided into 20 timesteps. The initial pressure across the entire domain is $p_0 = 10^7[\text{ML}^{-1}\text{T}^{-2}]$,

253 where [M] represents any consistent unit of mass. An injection well (I) at the center of the

254 domain conducts water injection at a constant rate of $Q_0 = 0.1[\text{L}^2\text{T}^{-1}]$, and eight pumping wells

255 (P1-P8) initiate pumping at a constant pressure of $0.5p_0$. The pressure dynamics are described by

256 the following equation:

$$\phi c_{\text{rw}} \frac{\partial p}{\partial t} = \nabla \cdot \left(\frac{\mathbf{k}}{\mu}\nabla p\right) + q, \tag{12}$$

257 where ϕ is the porosity of medium (-), c_{rw} is the total compressibility of rock and water

258 $[\text{M}^{-1}\text{LT}^2]$, p is the hydraulic pressure $[\text{ML}^{-1}\text{T}^{-2}]$, t is the time [T], $\mathbf{k}$ is the permeability tensor

259 $[\text{L}^2]$, μ is the water viscosity $[\text{ML}^{-1}\text{T}^{-1}]$, and q is the source/sink term $[\text{T}^{-1}]$, respectively. Here,

260    $\phi = 0.3$, $c_{\mathrm{rw}} = 6 \times 10^{-10}[\mathrm{M}^{-1}\mathrm{LT}^2]$, and $\mu = 10^{-3}[\mathrm{ML}^{-1}\mathrm{T}^{-1}]$. In this scenario, the tensor **k**

261   are simplified into a location-dependent scalar function, $k(x, y)$, where the values within the

262   1681 cells constitute the sole unknown parameters that need calibration. The governing equation

263   is numerically solved with the MATLAB Reservoir Simulation Toolbox (Lie & Møyner, 2021).

Figure 1. (a) Schematic overview of the model settings in Case 1. All four boundaries are impermeable. An injection well is positioned at the domain's center, and eight pumping wells (P1-P8) are situated near the boundaries. The blue cells indicate locations where measurements of k and p are acquired. The yellow cells depict the reference distribution of fractures. (b) Distribution of pressure (p) at the last timestep, highlighting the influence of fractured cells.

264   The observational dataset employed for inferring the distribution of $k(x, y)$ includes 49

265   permeability (k) values at the blue nodes (as shown in Figure 1a), 49 pressure (p) values at the

266   same nodes at 21 timesteps (49×21 values in total), and 9 flowrates (Q) values at the single

267   injection well and eight pumping wells at the 21 timesteps (9×21 values in total). The

268   observation errors associated with k, p, and Q are modeled with Gaussian distributions, i.e., $\varepsilon_k \sim$

269    $\mathcal{N}(0, \sigma_k^2)$, $\varepsilon_p \sim \mathcal{N}(0, \sigma_p^2)$, and $\varepsilon_Q \sim \mathcal{N}(0, \sigma_Q^2)$, where $\sigma_k = 5k_{\mathrm{m}}$, $\sigma_p = 0.05p_0$, and $\sigma_Q =$

270    $0.005Q_0$, respectively. In the reference model, there are 106 fractured cells, comprising

271   approximately 6.3% of the total cells. These high-permeability fracture zones are indicated by

272   the yellow cells in Figure 1(a). Figure 1(b) illustrates the pressure distribution in the reference

273   model at the last timestep, clearly demonstrating the impact of these high-permeability fractured
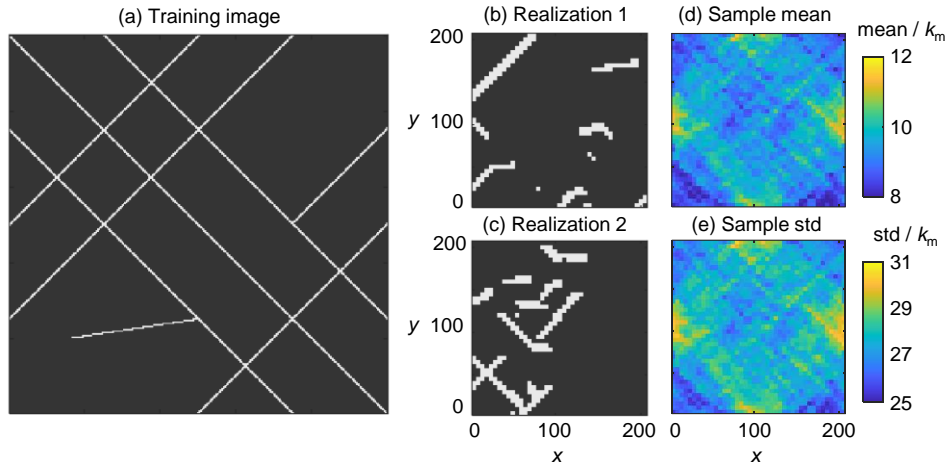

274   zones.

Figure 2. (a) The training image used to generate random realizations of the k field; (b-c) two realizations of the k field, and (d-e) the mean and standard deviation (std) of the k field.

275   The direct sampling method, as described by Mariethoz et al. (2010), is utilized to generate

276   random realizations of the $k(x, y)$ field, each field having a dimension of $N_k = 41 \times 41$. These

277   realizations are generated based on a training image that includes background information about

278   fractures, such as potential orientation and density (as shown in Figure 2a). In the generated k

279   realizations, black cells are designated as k_m, representing the matrix category, while white cells

280   are designated as k_f, signifying the fracture category. In Figures 2(b-c), we present two random

281   samples of the generated k fields. The sample mean and standard deviation (std) fields calculated

282   from all the realizations are depicted in Figures 2(d-e).

283   3.1.2 Results from Four DA Methods

284   Four DA methods, namely ESMDA, ILUES, ESDL, and PEDL, are applied to estimate the k

285   field across the flow domain. All methods, except for PEDL (without iteration, $N_e = 5000$),

286   undergo five iterations with an ensemble size of $N_e = 5000$. In the case of ILUES, the hyper-

287   parameter β, which dictates the selection of the local ensemble, is set to 0.1. For both ESDL and

288   PEDL, we have adopted the U-net architecture initially proposed by Ronneberger et al. (2015),

289   as depicted in Figure 7(a). Given the presence of three distinct types of measurement data—

290   permeability (k), flowrate (Q), and pressure (p)—each with varying dimensionalities, we employ

291   three U-net blocks to process each data type. Subsequently, we concatenate and further process

292   these data streams until the target (the 41×41 k field) is reached. In both ESDL and PEDL, the

293   DL model is trained using the Adam optimizer with a consistent learning rate of 0.001. The

294   training process consists of 100 epochs, with a batch size of 256.

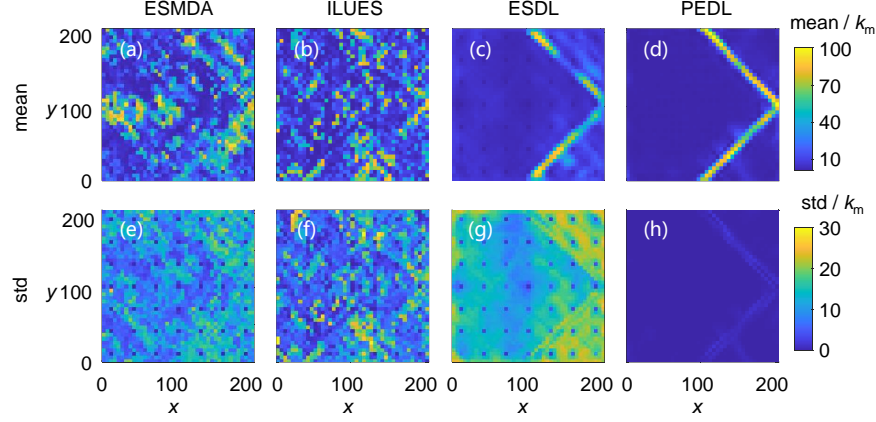

Figure 3. (a-d) Mean and (e-h) standard deviation (std) of the estimated k fields obtained by ESMDA, ILUES, ESDL, and PEDL, respectively. Note that all the means and stds are expressed as multiples of k_m.

295   The normalized root-mean-square errors (NRMSEs) relative to the matrix permeability k_m,

296   between the estimated mean ($\bar{k}$) and the reference (k^*) fields, i.e.,

$$\mathrm{NRMSE} = \frac{1}{k_\mathrm{m}} \sqrt{\frac{1}{N_\mathrm{k}} \sum_{i=1}^{N_\mathrm{k}} \left(\bar{k}_i - k_i^*\right)^2}, \tag{13}$$

297   are obtained as follows: ESMDA (32.31), ILUES (30.03), ESDL (15.89), and PEDL (12.11). It is

298   worth noting that the NRMSE value between the initial mean k field and the reference k field is

299   22.35. The NRMSE values for ESMDA and ILUES exceed that of the initial mean field,

300   indicating the occurrence of filter divergence in these two methods. With the DL-based update,

301   ESDL can obtain improved estimation of k, but the reduction in NRMSE from the initial field is

302   not very large. Without requiring iterations, PEDL can obtain the best match of the highly

303   complex parameter field.

304   Figure 3 illustrates the mean and standard deviation (std) of the k fields estimated by these four

305   DA methods. It is evident that PEDL effectively captures the distribution of fracture cells (highly

306   permeable zones) with low uncertainty, albeit with some minor details missing. Conversely,

307   neither ESMDA nor ILUES provide a satisfactory estimation of k. On the other hand, ESDL

308   partially recognizes the fracture structure. Specifically, ESDL tends to overestimate the k values

309   in non-fractured areas near the upper-right and lower-right corners, and the standard deviation of

310   the k field obtained by ESDL is significantly higher than those obtained using other methods.

Figure 4. Cumulative distribution functions (cdfs) for the reference k field, initial k realizations, and estimated k fields from PEDL, ESMDA, ILUES, and ESDL, respectively.

311   Given the strong non-Gaussian nature of this problem, it is necessary to consider more

312   information beyond the mean and standard deviation to thoroughly evaluate the results. Figure 4

313   displays the cumulative distribution functions (cdfs) of the updated k fields for all four methods,

314   as well as the reference and initial k fields. It is evident that PEDL produces a cdf of k field that

315   closely resembles the stepwise cdf of the reference k field, demonstrating PEDL's ability to

316   handle strong non-Gaussianity.

317   Moreover, to monitor the evolution of individual k field samples before and after the various

318   updates, we compare four randomly selected realizations in Figure 5. It reveals that initially

319   distinct realizations (the first row of Figure 5) tend to converge and approach the reference k

320   field after the update with PEDL (the last row of Figure 5). This consistency aligns with the

321   observed low k standard deviation values across the entire domain (as seen in Figure 3h).

322   Conversely, the first three rows of Figure 5 demonstrate that in both ESMDA and ILUES, the

323   updated realizations do exhibit some degree of convergence among them, but they do not

324   resemble the reference k field. This suggests the occurrence of filter divergence. In the case of

325   ESDL (the fourth row), while high-permeability stripes akin to the reference field do emerge in

326   the updated k realizations, the initial random structures of fracture in the four realizations largely

327   persist, resulting in substantial irregularities within the final realizations. One possible

328   explanation for this behavior is that the $\{\Delta \mathbf{m}^t, \Delta \mathbf{d}^t\}$ pairs may vary significantly for different

329    $\{\mathbf{m}^{t-1}, \mathbf{d}^{t-1}\}$ in nonlinear problems, yet they are not considered during the model training

330   process. The high values in $\mathbf{m}^{t-1}$ only partially cancel out the values at the same locations in

331    $\Delta \mathbf{m}^t$, causing the unwanted irregularities in each realization. Although these irregularities can be

332   averaged out in the ensemble mean, as shown in Figure 3(c), the large uncertainty do exist in the
333   standard deviation field (Figure 3g).

Figure 5. Four randomly sampled initial k fields and the corresponding updated ones with ESMDA, ILUES, ESDL, and PEDL, respectively. All k fields are expressed as multiples of k_{m}.

334 From the results above, it is concluded that while ESMDA, ILUES and ESDL encounter
335 significant difficulties in this problem, PEDL yields much better estimation results from the
336 perspective of ensemble behavior and individual realization performance.

337 3.1.3 Impact of Ensemble Size and Network Architecture

338 To assess the influence of ensemble size on PEDL's performance, we further conduct
339 experiments using ensembles with various sizes ($N_e = 10^2$ to 10^5, as depicted in Figure 6). To
340 ensure the statistical reliability of the results, we carried out twenty parallel tests for each
341 ensemble size. Notably, Figure 6 highlights that the NRMSE values begin to decline when N_e
342 exceeds 500 and stabilize as N_e surpasses 5,000. This observation is intriguing, as deep neural
343 networks (DNNs) are typically associated with a demand for an extensive volume of training
344 data.

Figure 6. NRMSEs of results obtained by PEDL with various ensemble sizes.

345 In our prior experiment, PEDL utilized a U-net architecture for DL. However, it's natural to
346 question whether alternative types of adequate DNNs can deliver comparable results within the
347 PEDL framework. To investigate the impact of network architecture, we decide to substitute the
348 U-net with a residual neural network (ResNet, shown in Figure 7b), while maintaining the
349 ensemble size of $N_e = 5000$. The training settings for the ResNet model remain identical to
350 those applied to U-net. Remarkably, the resulting NRMSE in this instance is 12.66, a value that
351 closely aligns with the NRMSE of 12.11 achieved by PEDL with U-net.
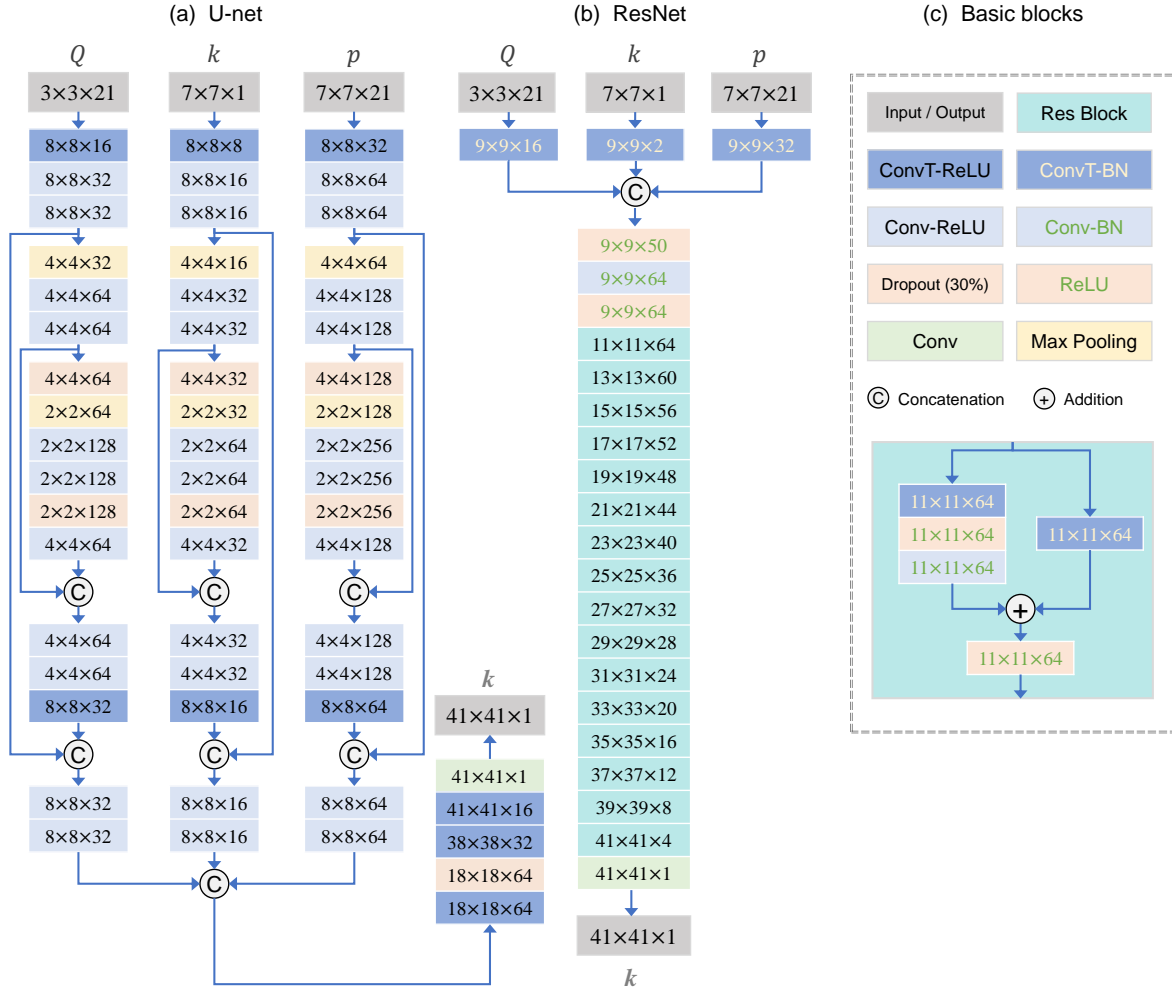

352

Figure 7. DL model architectures used in this study: (a) U-net, (b) ResNet, and (c) basic blocks used in U-net and ResNet, respectively. Here, Q, p, k represent flowrate, pressure, and permeability, as input or output, respectively. Conv and ConvT mean the 2-D convolution and the transposed 2-D convolution layers, ReLU denotes the rectified linear unit, and BN signifies the batch normalization layer, respectively.

353   In Figure 8, we present the spatial distributions of the mean and standard deviation of k fields

354   obtained through the ResNet-based PEDL, along with four random realizations of updated k

355   field. The results closely resemble the PEDL approach applied with the U-net (as seen in Figures

356   3 and 5). This observation underscores the fact that PEDL demonstrates satisfactory performance

357   with both U-net and ResNet architectures. It is likely that using a better designed DL model can

358   produce enhanced estimation of fractured media properties. Yet, the searching for the optimal

359   DL model and training options are beyond the scope of the current work.

Figure 8. Results obtained by PEDL using ResNet: (a) mean of the updated k fields, (b) standard deviation of the updated k fields, and (c-f) four random realizations of the updated k fields.

3.2 Case 2: Data Assimilation Considering Model Structural Error

In the previous section, the model structural error is not considered, and both the reference model and forecast model are based on the SC model. However, fractured media in the natural world often showcase significantly more pronounced complex and non-Gaussian behaviors than what can be accurately represented by the simplistic SC model. In this section, we shift our focus to the more accurate EDFM model, which serves as the reference model, to thoroughly assess the effectiveness of PEDL in addressing more complex scenarios. It's worth noting that when estimating the properties of the media through DA, we still employ the SC model, albeit introducing some degree of structural error into the model. In this section, we will subject PEDL to further testing within the context of model structural error to evaluate its robustness.

As the name implies, the EDFM model incorporates discrete fractures into the matrix as lower-dimensional entities, such as fracture lines within a 2-D matrix or fracture planes within a 3-D matrix. The EDFM model describes the flow within the matrix as follows:

$$\frac{\partial(\phi\rho)}{\partial t} = \nabla \cdot \left(\frac{\mathbf{k}}{\mu}\nabla(p - \rho g z)\right) + q^{(\mathrm{m})} - \sum_j q_j^{(\mathrm{mf})}, \tag{14}$$

373 where ρ means the density of water, g is the gravitational constant, z signifies the depth, $q^{(m)}$

374 denotes the source/sink term in the matrix cell, and $q_j^{(mf)}$ represents the exchange term from the

375 matrix cell to the j-th fracture (set as zero if matrix cell and fracture are nonadjacent),

376 respectively. The flow equation in the j-th fracture can be expressed as:

$$\frac{\partial\left(\phi_j^{(f)}\rho\right)}{\partial t} = \nabla \cdot \left(\frac{\mathbf{k}_j}{\mu}\nabla\left(p_j^{(f)} - \rho g z\right)\right) + \frac{1}{a_j}\left(q^{(f)} - q_j^{(fm)} - \sum_{i \neq j} q_{j,i}^{(ff)}\right), \tag{15}$$

377 where $\phi_j^{(f)}$ and $\mathbf{k}_j$ are the porosity and permeability of the j-th fracture, $p_j^{(f)}$ is the hydraulic

378 pressure in the current cell of the j-th fracture, $q^{(f)}$ is the source/sink term in the fracture cell,

379 $q_j^{(fm)}$ is the exchange from the j-th fracture to the surrounding matrix cell, $q_{j,i}^{(ff)}$ is the exchange

380 from the j-th fracture to other fractures (set as zero if they don't intersect in the current cell), and

381 a_j is the aperture of the j-th fracture, respectively.

382 The matrix-fracture exchanges $q_j^{(mf)}$ and $q_j^{(fm)}$, when calculated on cells, can be expressed as:

$$Q_j^{(mf)} = \int_{V_m} q_j^{(mf)}dV = T^{(mf)}\left(p - p_j^{(f)}\right), \tag{16}$$

383 and

$$Q_j^{(fm)} = \int_{A_m} q_j^{(fm)}dA = T^{(mf)}\left(p_j^{(f)} - p\right) = -Q_j^{(mf)}, \tag{17}$$

384 respectively. In the above equations, $T^{(mf)} = \frac{k^{(mf)}A^{(mf)}}{d^{(mf)}}$ is the transmissivity between matrix and

385 fracture, $k^{(mf)}$ is the volume-weighted harmonic mean of fracture and matrix permeability, $A^{(mf)}$

386 is the exchange area between matrix and fracture cells, and $d^{(mf)}$ is the characteristic distance

387 between matrix cell and fracture plane, respectively. The matrix-fracture exchanges calculated

388 with equations (15-17) are sometimes called "non-neighboring connections" since the matrix and

389 fracture cells are not neighbors in griding but connected by extra relations. For more details

390 about the EDFM model, interested readers can refer to (Lie & Møyner, 2021; Moinfar et al.,
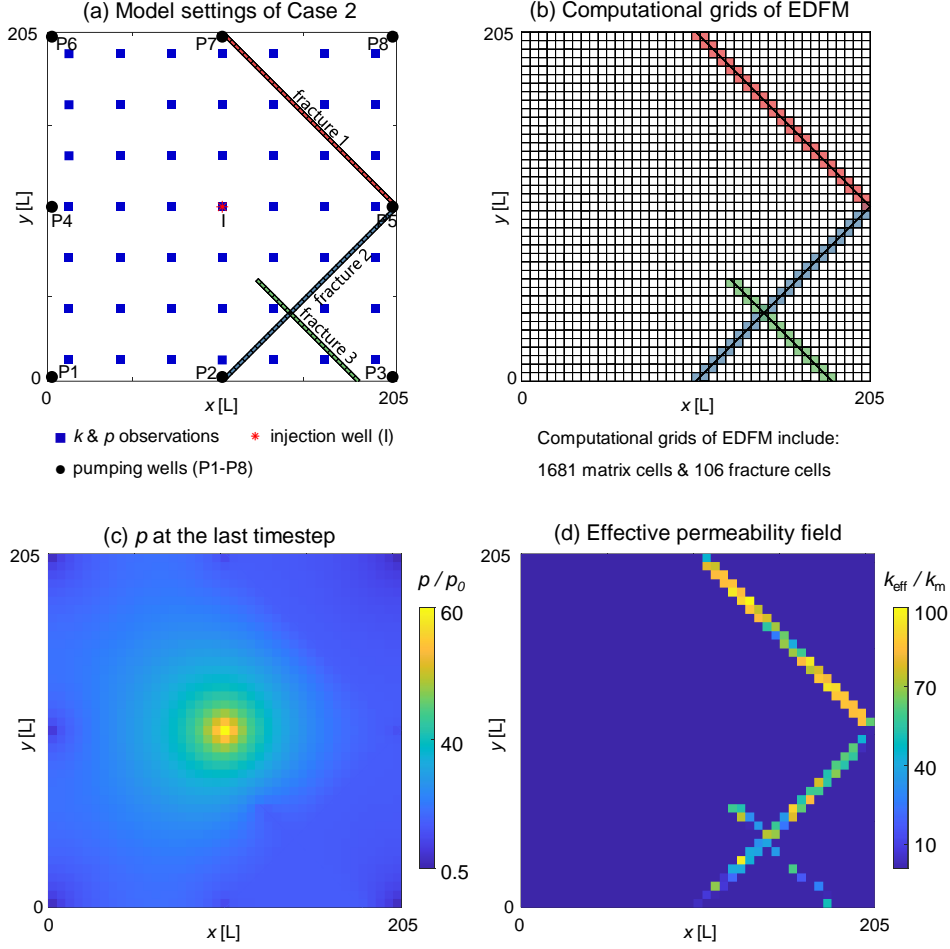

391 2014).

Figure 9. (a) Model settings of Case 2; (b) Computational grids of the EDFM model (colored cells are linked to fracture cells appended through non-neighboring connections); (c) Spatial distribution of pressure calculated with the EDFM model at the last timestep; (d) Effective permeability field found by an optimization method based on p and Q at all timesteps in the EDFM model.

In Case 2, we examine a fractured aquifer similar to the one in Case 1 (depicted in Figure 1), with the exception of the fracture part. In this aquifer, there are no high-permeability matrix cells. Instead, there are three fractures with permeability of $k_f^* = 100k_m$, porosity of $\phi = 0.8$, and aperture of $a = 0.2[L]$ (as illustrated in Figure 9a). As in Case 1, the simulation period is set to be $T_s = 86400$ [T], evenly divided into 20 timesteps. At $t = 0[T]$, the pressure is uniformly set as $p_0 = 107[ML^{-1}T^{-2}]$ across the domain. The injection and pumping wells are managed in the same manner as Case 1, i.e., one injection well located at the center of the domain with the rate of $0.1[L^2T^{-1}]$, and eight pumping wells (P1-P8) extracting water at a fixed pressure of $0.5p_0$. As

400   shown in Figure 9(b), the matrix is discretized into 41×41 uniform grids, which divides the

401   fractures into 106 fracture cells. In total, there are 109 identified non-neighboring connections,

402   including three fracture-fracture connections. The pressure distribution calculated with the

403   EDFM model at the last timestep is displayed in Figure 9(c). In this case, the EDFM model,

404   acting as the reference model, is used to generate measurement data.

Figure 10. Results of permeability estimation in Case 2 using U-net-based PEDL (top row) and ResNet-based PEDL (bottom row), respectively. The mean estimates for the two methods are presented in subfigures (a) and (e), the estimation uncertainty measured by the standard deviation (std) are given in (b) and (f), and some random realizations are depicted in (c-d) and (g-h), respectively.

405   In the implementation of DA, the simpler SC model with 41×41 grids is adopted to calculate the

406   model responses, due to its ease of implementation and prevalence in fractured aquifer

407   characterization practices (National Academies of Sciences, 2020). Unlike the EDFM model, the

408   SC model has no fracture cells or non-neighboring connections. The impact of actual fractures is

409   reflected in the effective permeability field (EPF) of matrix. To evaluate the performance of

410   PEDL, a "pseudo-reference" of EPF for the SC model is found by solving a nonlinear data fitting

411   problem with the trust-region-reflective algorithm (Coleman & Li, 1996) based on the complete

412   data of p and Q at all grids and timesteps from the EDFM model simulation. At each timestep,

413   there are 1681 p values and nine Q values. The obtained EPF is shown in Figure 10(d), which is

414   used to calculate the NRMSE values of the updated k fields obtained by PEDL.

415   The measurement data from the same observation network (Figure 9a) as in Case 1 are used in

416   the estimation of k field here, i.e., 49 k values and 49×21 p values at the 7 × 7 blue nodes, and

417   9×21 Q values at the single injection well and eight pumping wells. Figure 10 shows the

418   estimated mean, std and two arbitrarily picked realizations of k field by U-net-based PEDL (top

419   row) and ResNet-based PEDL (bottom row). Evidently, PEDL demonstrates the capacity to

420   capture the fundamental structure of fractures, employing either the U-net or ResNet architecture.

421   Notably, there are no remarkable distinctions between the mean estimate and individual

422   realizations, underscoring the consistency of PEDL's performance. Additionally, PEDL exhibits

423   NRMSE values of 16.02 for U-net and 15.07 for ResNet. While these NRMSEs may not reach

424   the levels observed in Case 1 (with NRMSE values close to 12), they remain quite acceptable,

425   given the presence of model structural error introduced by adopting the simplified SC model in

426   DA.

4 Conclusions and Discussions

428   Water flow and solute transport in fractured media exhibit distinct characteristics, characterized

429   by the notable non-Gaussian distribution of media properties and the substantial non-linearity in

430   the underlying processes. Accurately estimating the heterogeneous hydraulic parameters of

431   fractured media is of utmost importance for reliable predictions and well-informed decision-

432   making. Nevertheless, the complexities arising from the high dimensionality and non-Gaussian

433   nature of fractured media present substantial challenges for traditional DA methods, such as

434   MCMC and EnKF, when aiming to achieve a robust estimation of these intricate properties.

435   Previous attempts to facilitate the effective application of these DA methods have primarily

436   relied on reparameterization techniques, involving the transformation of non-Gaussian variables

437   into Gaussian ones. However, the use of these techniques can result in the loss of essential

438   information related to the true nature of fractured media.

439   DL, known for its proficiency in modeling complex, nonlinear relationships and identifying

440   intricate patterns within data, can improve DA by addressing the challenges arising from high-

441   dimensionality and non-Gaussianity concurrently. J Zhang et al. (2020) proposed the innovative

442   use of DL to create a nonlinear updating scheme, replacing the traditional linear Kalman

443   formulation widely employed across various research domains. This DA method, named ESDL,

444   offers a superior capacity to capture the non-Gaussian characteristics of subsurface media's
445   parameter fields compared to its Kalman-based counterparts. In our study, we applied ESDL for
446   the first time to estimate hydraulic parameter fields within fractured media, comparing it with
447   two Kalman-based DA methods, ESMDA(Emerick & Reynolds, 2013) and ILUES (J Zhang et
448   al., 2018). Our findings demonstrate that ESDL significantly enhances the characterization of
449   fractured media over ESMDA and ILUES. However, we observed some irregularities in the
450   fracture networks inferred by ESDL, potentially attributable to the transition process from the
451   innovation vector (the difference between observations and model predictions) to the update
452   vector (the difference between posterior and prior parameters). Based on this insight, we
453   enhanced ESDL by introducing a new updating scheme. The resulting DA method, named
454   parameter estimator with DL (PEDL), establishes a direct update from the multi-source
455   observation vector to the posterior parameter vector. PEDL surpasses ESDL in the same fracture
456   characterization problem. In our sensitivity analysis regarding ensemble size, we observed that
457   PEDL improves permeability estimates when utilizing ensemble sizes up to 5000. This is
458   noteworthy, as DL models typically require a substantial volume of training data. Thus, an
459   ensemble size not exceeding 10,000 appears as a reasonable compromise between inference
460   accuracy and computational efficiency. Furthermore, PEDL's adaptability is evident in its
461   flexibility regarding the architecture of the DL model employed. We verified this by testing two
462   distinct model architectures, U-net and ResNet, within the PEDL framework, both of which yield
463   similar estimation results in two case studies with increasing complexity. Additionally, we
464   evaluated PEDL's performance in the presence of structural model error. Specifically, we used
465   the sophisticated EDFM model as the reference model to generate measurement data but adopted
466   the simplified SC model as the forecast model in DA. In this scenario, the ground truth exhibited
467   heightened non-Gaussian and nonlinear characteristics, mirroring the complexities typically
468   encountered in practical applications. Although PEDL, utilizing either U-net or ResNet, could
469   not achieve an exact match between the forecast model and the ground truth, it displayed the
470   ability to discern the fundamental structure of actual fractures, albeit with slightly reduced
471   performance in comparison to Case 1, due to the presence of model structural error.

472   In the current study, we investigate two cases featuring only three fractures. While our tests have
473   unequivocally demonstrated the effectiveness of PEDL, it is imperative to address more intricate
474   scenarios in future research endeavors. The presence of more fractures introduces formidable

475 challenges to both modeling and DA techniques. To construct an adequate numerical model, it is
476 essential to enhance the discretization in both spatial and temporal domains. Naturally, this will
477 lead to a substantial increase in simulation time. To bolster simulation efficiency, one can
478 consider adopting surrogate models or low-fidelity approximations. Striking a balance between
479 efficiency and accuracy, a promising solution may involve leveraging multi-fidelity simulations
480 underpinned by DL techniques, as suggested by Chakraborty (2021). Furthermore, to
481 comprehensively characterize more complex geological media, we must expand our data
482 collection efforts to improve information content. This entails considering various types of
483 measurements, including electromagnetic and electrical resistivity tomography data. The
484 intricate nature of the models and the data necessitates the development of a more sophisticated
485 DL model and an updated formula for PEDL.
