Key Points:

- We demonstrate that traveling ionospheric disturbances can be produced in simulations of the ionosphere-thermosphere system.

- We show that these traveling ionospheric disturbances propagate to the topside ionosphere in simulations.

Abstract

We present simulation results of the vertical structure of Large Scale Traveling Ionospheric Disturbances (LSTIDs) during synthetic geomagnetic storms. These data are produced using a one-way coupled SAMI3/GITM model, where GITM (Global Ionosphere Thermosphere Model) provides thermospheric information to SAMI3 (SAMI3 is Another Model of the Ionosphere), allowing the production and propagation of LSTIDs. We show simulation results which demonstrate that the traveling atmospheric disturbances (TADs) generated in GITM propagate to the topside ionosphere in SAMI3 as LSTIDs. The speed and wavelength (900 m/s and 10º-20º latitude) are consistent with LSTID observations in storms of similar magnitudes. We demonstrate the LSTIDs reach altitudes beyond the topside ionosphere with amplitudes of <5% over background which will facilitate the use of plasma measurements from the topside ionosphere to supplement measurements from GNSS in the study of TIDs. Additionally, we demonstrate the dependence of the characteristics of these TADs and TIDs on longitude.

Plain Language Summary

LSTIDs are a type of wave that occurs in the ionosphere, a layer of the atmosphere dominated by plasma where the motions of particles are highly subject to the magnetic field, during geomagnetic storms. We utilize two models of Earth's atmosphere and ionosphere to show how these waves behave and show that their location, timing, and speed is dependent on various storm characteristics, timing, and location. We also show that a high-altitude satellite measuring plasma density in the ionosphere should be able to detect the characteristics of these waves.

1 Introduction

During geomagnetic storms, Traveling Atmospheric Disturbances (TADs), are generated by locally heating the thermosphere within the auroral zone and propagating the deposited energy outwards. The energy is deposited primarily through Joule heating caused by precipitating particles colliding with neutrals, which results in frictional heating and momentum exchange with ions and electrons (Brekke & Kamide, 1996; Hunsucker, 1982; Strangeway, 2012; J. Zhu et al., 2016). TADs propagate as variations in density, temperature, and winds in the neutral atmosphere. These neutral wind perturbations drive their ionospheric counterpart, Traveling Ionospheric Disturbances (TIDs), through ion-drag forcing. TADs/TIDs can also be driven from below by volcanos, thunderstorms, thermospheric turbulence, etc. which form atmospheric gravity waves (AGWs) in the lower thermosphere (Borchevkina et al., 2021; Cheng & Huang, 1992; Nicholls & Pielke, 2000; Pradipta et al., 2023; Zhang et al., 2022). Few observations exist of AGWs due to their location in the lower thermosphere, however TADs have been observed with satellites such as the Gravity field and steady-state Ocean Circulation Explorer (GOCE) and the Challenging Minisatellite Payload (CHAMP) (Trinh et al., 2018). Most of the studies of TIDs are performed with data from ground-based networks such as ionosondes (Hajkowicz, 1991), radars (Bowman, 1990; Fukao et al., 1991; Oliver et al., 1995), and airglow imagers (Shiokawa et al., 2004). Recently, Ground-based Global Navigation Satellite System (GNSS) networks have allowed investigations on a more global scale (Figueiredo et al., 2018; Pradipta et al., 2016). However, such measurements are altitude integrated and cannot decipher the wave characteristics at different altitudes. Ionospheric measurements from satellites can provide information on TIDs where GNSS receivers cannot be placed, but such measurements typically do not correlate well with GNSS perturbation TEC

60 measurements where they do coincide (Ren et al., 2022). Thus, it is important to understand the
61 characteristics of the altitude dependence of TIDs.

62   Large Scale TIDs (LSTIDs) are TIDs with wavelengths greater than ~1000 km and are
63 normally associated with geomagnetic storms, although they have been observed at
64 geomagnetically quiet times with smaller amplitudes (Bruinsma & Forbes, 2010; Hedin & Mayr,
65 1987). The electron and ion density perturbations associated with LSTIDs are mainly observed
66 with ground-based radars and GNSS receivers (Pradipta et al., 2016; van de Kamp et al., 2014;
67 Zakharenkova et al., 2016), with the clear disadvantage that these observations can only be
68 acquired over land and in areas with sufficient power and communication infrastructure. The
69 ionosphere is a medium whose refractive index is dependent on the integrated electron density
70 along the path of the radio wave. GNSS receivers measure the delay associated with the
71 integrated electron density along the line-of-sight to the GNSS satellites which is processed into
72 integrated Total Electron Content (TEC) and subsequently geometrically converted to vertical
73 TEC. TEC measurements yield little insight into the vertical structure of LSTIDs and the lack of
74 data over the oceans prevents a global view of LSTID propagation during geomagnetic storms.
75 While work is being done to form a more complete global picture of LSTID propagation using
76 low power GNSS receivers and amateur radio networks, these are not yet widespread and still
77 lack coverage over the oceans.

78   Satellite observations of LSTIDs have been performed, but the link between
79 measurements made at different altitudes in the ionosphere and the vertically integrated TEC is
80 unclear (Ren et al., 2022). Analysis of Dynamic Explorer (DE 2) data yielded observations of
81 wavelike fluctuations, only in the high-latitude regions (Innis & Conde, 2002). The Global
82 Ultraviolet Imager (GUVI) instrument onboard the Thermosphere Ionosphere Mesosphere
83 Energetics and Dynamics (TIMED) satellite has recently been used to identify
84 GWs/LSTIDs/LSTADs and link them to observations by ground-based interferometers and
85 radars; however, these observations do not extend into the topside ionosphere (Bossert et al.,
86 2022). Sounding from satellites above the F-peak is possible and Gross (1985) compared topside
87 sounding observations to in-situ ionization density measurements suggesting that perturbations
88 follow flux tubes vertically, but was not able to prove if the perturbations seen were travelling or
89 stationary.

90   The use of global circulation ionosphere and thermosphere models is therefore necessary
91 to link observations between measurements made in different layers of the atmosphere and to
92 understand the behavior of LSTIDs both vertically and longitudinally. The thermosphere–
93 ionosphere–electrodynamics general circulation model (TIE-GCM) has been used to model
94 LSTADs/LSTIDs (Jonah et al., 2020; Richmond, 2003; Roble & Ridley, 1994). However TIE-
95 GCM does not model altitudes above ~500-700 km (depending on solar activity), well short of
96 satellites with capabilities to measure properties of the topside ionosphere (720 km and 840 km
97 for COSMIC-2 and DMSP, respectively). The Whole Atmosphere Community Climate Model
98 with thermosphere and ionosphere extension (WACCM-X) has been used to model LSTIDs as
99 well (Liu et al., 2018), but reaches altitudes similar to that of TIE-GCM.

100   Investigations using SAMI3 (SAMI is another model of the ionosphere) have
101 demonstrated that it can sustain high-altitude TIDs using the HIgh Altitude Mechanistic general
102 Circulation Model (HIAMCM) (Huba et al., 2023) and WACCM-X (Huba & Liu, 2020) for the
103 neutral dynamics to simulate GWs generated in the lower atmosphere. In this study, we use the
104 Global Ionosphere-Thermosphere Model (GITM), which can self consistently generate TADs, as

105 a seeding mechanism for SAMI3. When coupled, we can use the results from SAMI3 to
106 investigate how LSTIDs, seeded by LSTADs, behave in the ionosphere up to topside and
107 exospheric altitudes.

108 **2 Methodology**

109   2.1 GITM

110   GITM is a global-scale 3-dimensional model with an adjustable, radially-aligned
111 orthogonal geographic, grid. GITM solves the coupled continuity, momentum, and energy
112 equations for the neutral and ion species in a user-specified grid stretched in altitude. GITM
113 differs from most thermospheric models in that it does not assume hydrostatic equilibrium in the
114 vertical velocity solver, which allows the realistic generation of TADs due to Joule and particle
115 heating in the auroral zone. GITM allows different models of high-latitude electric fields, auroral
116 particle precipitation, solar EUV, and particle energy deposition to be used (Ridley et al., 2006).
117 The work presented here uses the Weimer (2005) model, driven by solar wind inputs for the
118 high-latitude electric potential, and Fuller-Rowell and Evans (1987) model, driven by the
119 Hemispheric Power Index (HPI) for the auroral particle heating, which drives TAD production.
120 The initial state of the model is set by the Mass Spectrometer and Incoherent Scatter radar
121 (MSIS) neutral atmosphere model and the International Reference Ionosphere (IRI) model.

122   2.2 SAMI3

123   SAMI3 is a 3-dimensional, physics-based model of the ionosphere. SAMI3 also solves
124 the coupled continuity, momentum, and energy equations, however it only models ions and
125 electrons (not neutral species). By default, SAMI3 uses NRLMSISE00 (Picone et al., 2002) for
126 neutral densities and the HWM14 (Drob et al., 2015) for the neutral wind; it has been modified
127 to use GITM neutral densities and winds to allow more accurate representations of neutral
128 dynamics and generation of TADs. SAMI3 also uses Weimer for high-latitude electric potential.

129   SAMI3 is configured to read the density of the neutral species N2, O2, O, NO, N4S, H,
130 and He, as well as the zonal and meridional neutral winds and neutral temperature from GITM
131 every five minutes. This data is interpolated from the geographic grid used by GITM to the
132 geomagnetic grid used by SAMI3 with magnetic Apex coordinates (Richmond, 1995; VanZandt
133 et al., 1972). Because SAMI3 extends above the GITM domain, the neutral velocities and
134 temperatures in this region are assumed to be constant, while the densities are assumed to
135 decrease hydrostatically. SAMI3 is set to output data at a five-minute cadence as well.

136   2.3 Synthetic Geomagnetic Storm

137   We use a synthetic geomagnetic storm to investigate our ability to produce LSTIDs using
138 the coupled GITM/SAMI3 model and examine their characteristics in altitude, local time, and
139 longitude. We have chosen a day with very low background geomagnetic activity (May 21,
140 2011) and run the models with the quiet-time indices and seasonally appropriate conditions
141 associated with this time. Representing a moderate to large geomagnetic storm, we increase the
142 background values of Bz=-2 nT and HPI=10 GW to Bz=-20 nT and HPI=200 GW as a step
143 function. All other geomagnetic indices were kept at constant values. Both models were run for
144 at least 24 hours before the onset of the simulated storm to eliminate transients and reach steady
145 state.

146 **3 Results and Discussion**

147   Figures 1 a–f show the TADs produced in the simulation using GITM. The perturbations
148 were calculated by first removing background densities with a first-order forward-backward
149 bandpass filter with cutoff frequencies at 40 and 85 minutes, and then calculating the percent
150 difference between the model outputs and filtered data. TADs form immediately after storm
151 onset and propagating towards the equator. These perturbations form in, and propagate away
152 from, the auroral zone where most of the energy from Joule heating and particle precipitation is
153 deposited. While not shown, similar propagation is observed in all neutral densities as well as the
154 neutral winds.

Figure 1. Global snapshots of perturbation total neutral density output from GITM as a function
of time from storm onset. The location of the magnetic equator is indicated with the black dashed
line.

159   The speed of these TADs (~900 m/s) is consistent with LSTIDs measured with detrended
160 TEC data from GNSS observations in geomagnetic storms of similar amplitude in Bz and HPI.
161 Bz often oscillates throughout the duration of a geomagnetic storm, signaling changes in amount
162 of energy deposited into the Ionosphere-Thermosphere (IT) system. These variations in
163 deposited energy cause variations in the neutral winds and temperatures in the auroral zone,
164 producing TADs that propagate equatorward. Our model only has one change in drivers (Bz and
165 HPI), leading to a singular TAD being produced.

166   Figures 2 a–d show keograms of the perturbations in the total neutral mass density at
167 various longitudes starting 3 hours before storm onset and extending to 8 hours after storm onset.
168 Due to the filtering technique used (with the filter centered at each time and the abrupt change in

169 density not having a single frequency the bandpass filter can react to), perturbations from
170 background appear before storm onset, though this is not physical as only a single perturbation
171 was formed. The LSTAD propagates equatorward with some asymmetries in amplitude and
172 speed with longitude and hemisphere. The hemispherical asymmetries are due the temperature
173 being lower in the winter (Southern) hemisphere. Longitudinal asymmetries are due to the local
174 time/geographic distribution of the locations of the heating in the auroral zone (see Figure 4).

Perturbation Total Neutral Mass Density from GITM at 500km

175
176 **Figure 2**. Keograms of Total Neutral Density at 500 km altitude and several geographic
177 longitudes. Solid brown vertical lines at 12 UT mark storm onset. Dashed vertical green lines
178 mark local dusk while dotted vertical green lines mark local dawn. At each longitude, the
179 location of the magnetic equator is indicated with the horizontal black dashed line.

180   At lower altitudes the propagation speed and amplitude of TADs are smaller than at
181 higher altitudes which is due to decreased temperatures, seen in Figures 3a-f. There appears to be
182 two distinct modes, rather than a gradual transition, which could be evidence of different
183 propagation modes in the thermosphere or, as proposed by Hedin & Mayr (1987), a ducted
184 propagation mode. At 150 km (Figures 3a-c), perturbations reach the equator between 15-16 UT
185 while at 660 km (Figures 3d-f), the perturbations reach the equator near 13-14 UT. The
186 keograms show that the TADs propagate both poleward and equatorward from the auroral zone.
187 The perturbations that appear delayed, between 2 and 3 hours after storm onset, are from TADs
188 that propagated from their auroral source region across the polar cap.

189   There is a strong longitudinal dependence of the TAD distribution. This is largely due to
190 the distribution of energy input in the auroral zone being a function of local time. Figure 4 shows
191 the locations of the greatest intensities of Joule heating in the auroral zone, and thus the regions

192 where TADs are produced. Because these locations are dependent on magnetic local time
193 (MLT), and in turn UT/longitude, the longitudinal distribution of TADs will be dependent on the
194 UT of their production (Perlongo & Ridley, 2016).

195

196 **Figure 3**. Keograms of perturbation total neutral density from GITM along ±120° & 0°
197 geographic longitude and at 150 km (top panels) and 660 km (bottom panels) altitude. The
198 location of the magnetic equator is indicated with the black dashed line.

199

200 **Figure 4**. Altitude integrated Joule heating just after storm onset. Correlation between the
201 locations with the greatest amplitude of Joule heating and the locations where TADs are formed
202 in Figures 1-3 is evident

203   The greatest heating in the northern hemisphere occurs in the 60° E and 100°W
204 geographic longitude (GLON) sectors and are offset from the geographic pole by about 20°

205   geographic latitude (GLAT). In the southern hemisphere, the peak heating occurs near 75° and
206   65° S GLAT, and 90° E and 140° W GLON. The greater offset between the geographic and
207   geomagnetic field is evident at these geographic locations. This offset thus leads to longitudinal
208   and hemispherical asymmetries, as the location of the auroral zone is dependent on Earth's
209   magnetic field configuration and the timing of storm onset (Perlongo & Ridley, 2016).

210   Motion of the modeled TADs is associated with the neutral winds (and the LSTAD
211   dynamics), which then drive ion motion through momentum exchange. The ionospheric
212   counterpart of the TADs we have produced with GITM are shown in Figures 5a-f, which show
213   keograms at the same longitudes as those shown in Figure 2. The perturbations are extracted
214   from SAMI3 outputs with the same methods used for the GITM outputs. The speed and
215   wavelength of these TIDs (900 m/s and ~10-20o latitude, respectively) would classify them as
216   Large Scale. LSTIDs for a storm of this magnitude have been observed to have an amplitude
217   between 0.7-1.5 TEC Units (TECU) with GNSS receivers. Our slightly smaller amplitude is
218   consistent with previously reported results showing that existing particle precipitation models do
219   not account for the full spectrum of precipitating electrons, leading to lower auroral energy
220   inputs (Q. Zhu et al., 2022).

221

222   **Figure 5**. Keograms of SAMI3 differential TEC along several geographic longitudes. As in
223   Figure 2, the solid line marks storm onset, dashed vertical green lines mark local dusk, and
224   dotted vertical green lines mark local dawn. The location of the magnetic equator at each
225   longitude is indicated with the horizontal black dashed line.

226   The LSTIDs originate in the auroral zone in both hemispheres, propagate to the equator
227   and continue into the opposite hemisphere. At the longitudes in Figures 5a, 5b and 5f, the TIDs
228   meet North of the geomagnetic equator due to the background temperature being higher in the

229   summer hemisphere. On the nightside this effect is less pronounced (as interhemispheric
230   temperature differences are lower in the nightside), with the LSTIDs meeting very close to the
231   geomagnetic equator in Figures 5c-e. Hemispheric asymmetries in LSTID amplitude and
232   wavelength also exist, where the longitudes with the greatest hemispheric symmetry correspond
233   to the longitudes with the most similar Joule heating rates in the North and South hemisphere,
234   near 0° and 180° longitude (Figures 5a and 5d). In general, the discrepancy in amplitude and
235   propagation speed between the two hemispheres is due to the storm occurring during Northern
236   summer and thus the greater deposition of energy in the Northern auroral zone, as seen in Figure
237   4.

238

Figure 6. Propagation of TIDs shown with perturbation electron density along a single
geographic longitude modeled in SAMI3. The magnetic equator at this longitude is at
approximately -5° Geographic latitude.

242   Figure 6 shows the altitudinal distribution of LSTIDs produced in SAMI3 along a single
243   geographic longitude. Other longitudes show similar behavior. Perturbations in electron density
244   exist throughout the entire ionosphere and well into the topside. A reversal in perturbation
245   density can be seen at around 300-400 km, where the F-peak lies. The electron density variation
246   depends on the sign of $V \cdot \nabla N_e$ and since the sign of ∇N_e changes above the F-peak, the sign of
247   the perturbation changes (Huba et al., 2015). This reversal is a contributing factor to why the
248   perturbations in vertically integrated TEC perturbations are of a lower amplitude than the

249 perturbations seen in the electron density and why satellite measurements in the topside
250 ionosphere typically do not correlate well with GNSS perturbation TEC measurements.

251 **4 Conclusions**

252   Through a one-way coupled GITM and SAMI3 model, we have utilized a synthetic
253 geomagnetic storm to investigate TAD and LSTID behavior. We have shown that, due to the
254 location of their formation in the auroral zone, there is a longitudinal dependence of TAD/LSTID
255 location associated with the location of maximum Joule heating. TADs/LSTIDs can be seen
256 forming immediately after storm onset and propagating both equatorward and poleward with
257 speeds and amplitudes that vary with altitude. The most intense LSTID and TAD occurred at
258 120° W longitude. This region does not correspond to the most intense Joule heating, but near
259 sunrise when the neutral temperatures are the lowest, and thus where the perturbations over
260 background are largest. LSTIDs produced in the SAMI3 results show speeds that are consistent
261 with detrended TEC data from GNSS observations in geomagnetic storms of similar amplitude
262 in Bz and HPI. They propagate equatorward, however the locations where LSTIDs produced in
263 each hemisphere meet with respect to the geographic equator vary with longitude due the offset
264 of the geomagnetic and geographic equators. The LSTIDs are seen to extend well into the
265 topside ionosphere; however, the sign of the associated density perturbations reverses near the F-
266 peak, explaining why satellite measurements in the topside ionosphere typically do not correlate
267 well with GNSS perturbation TEC measurements.

268   The simulated storm can be further utilized to model LSTIDs during different seasons
269 and with different storm onset times, allowing us to determine the role of the offset between the
270 geographic and geomagnetic poles on LSTID characteristics. Our results aid our understanding
271 of the longitudinal, altitudinal, and hemispherical behavior/distribution of LSTIDs as well as
272 various aspects of IT coupling during geomagnetic storms. Using the modeled results in the
273 topside ionosphere, we will be able to deconvolve the differences between TEC and satellite
274 measurements and utilize observations from satellites, such as DMSP, to fill gaps in TEC
275 observations in areas where GNSS receivers cannot be placed.

282 **Open Research**

283 The GITM model is open source and can be accessed at https://github.com/gitmcode/gitm. The
284 SAMI3 model is available at https://doi.org/10.5281/zenodo.7895859. Data used to recreate the
285 plots shown in this publication can be accessed at (Bukowski, 2023). An analysis suite for
286 processing of both model outputs is available at https://github.com/abukowski21/SAMI3-GITM-
287 python/.
