Key Points:

- A theoretical description of strain far field radiation from a seismic rupture is introduced.

- Source parameters were evaluated from strain data for earthquakes in magnitude range $2.0 - 4.3$

- DAS allows for investigation of source parameters and site effects with fine spatial resolution.

Abstract

Distributed Acoustic Sensing (DAS) is becoming a powerful tool for earthquake monitoring, providing continuous strain-rate records of seismic events along fiber optic cables. However, the use of standard seismological techniques for earthquake source characterization requires the conversion of data in ground motion quantities. In this study we provide a new formulation for far-field strain radiation emitted by a seismic rupture, which allows to directly analyze DAS data

26 in their native physical quantity. This formulation naturally accounts for the complex directional

27 sensitivity of the fiber to body waves and to the shallow layering beneath the cable. In this

28 domain, we show that the spectral amplitude of the strain integral is related to the Fourier

29 transform of the source time function, and its modelling allows to determine the source

30 parameters.

31 We demonstrate the validity of the technique on two case-studies, where source parameters are

32 consistent with estimates from standard seismic instruments in magnitude range 2.0 - 4.3. When

33 analyzing events from a 1-month DAS survey in Chile, moment - corner frequency distribution

34 shows scale invariant stress drop estimates, with an average of $\Delta\sigma = (0.8 \pm 0.6)$MPa. Analysis

35 of DAS data acquired in the Southern Apennines shows a dominance of the local attenuation that

36 masks the effective corner frequency of the events. After estimating the local attenuation

37 coefficient, we were able to retrieve the corner frequencies for the largest magnitude events in

38 the catalog.

39 Overall, this approach shows the capability of DAS technology to depict the characteristic scales

40 of seismic sources and the released moment.

41 **Plain Language Summary**

42 A new formulation for far-field strain radiation from seismic ruptures is derived, leading to a

43 direct interpretation of DAS (Distributed Acoustic Sensing) data to retrieve source properties

44 (seismic moment and source size), via a spectral modelling. This approach is validated on real

45 data recorded in two different tectonic environments, the Chilean margin and the southern

46 Apennines, in Italy. Despite the unique directional sensitivity and peculiar signal characteristics,

47 we demonstrated the high potential of DAS systems in characterizing the seismic ruptures over

48 different space scales, with accuracy increased by redundancy of information from the very-high

49 spatial resolution in the recording of seismic waves.

50 **1 Introduction**

51   Distributed Acoustic Sensing (DAS) is an emerging technology in seismology that allows

52 to get continuous recordings of seismic waves along an optical fiber. DAS systems exploit phase

53 variations in the backscattered light to record the axial strain along the fiber (Hartog, 2017).

54 Thus, a DAS system appears as a single-component seismic array, with main advantage to have a

55 very dense spatial coverage of sensors and a single endpoint for the collection of data, the

56 interrogator, which sends and receives the laser pulses to measure the strain rate. Also, the

57 availability of existing telecom dark fibers allows to investigate environments usually difficult to

58 monitor, such as oceanic seafloors, volcanic flanks, and geothermal areas, over distances

59 between a few and hundreds of kilometers (e.g., Sladen et al., 2019; Currenti et al., 2021; Tsuji et

60 al., 2021). In the recent years, DAS technology has been successfully applied to seismology for

61 earthquake location (Nishimura et al., 2021; Piana Agostinetti et al., 2022; Sladen et al., 2019),

62 focal mechanism determination (Li et al., 2023), seismic velocity estimation (Lellouch et al.,

63 2019) and site effect characterization (Ajo-Franklin et al., 2019; Spica et al., 2020).

64 While techniques based on time picking and polarity recognition can be directly applied

65 to strain-rate data, determination of source parameters from DAS measurements requires further

66 development, either processing data directly in the strain-rate domain or converting them into

67 more classical kinematic quantities.

68 To provide a macroscopic characterization of the source of a seismic event, one needs to

69 determine the seismic moment, the radiated energy, the event size, and the released stress drop,

70 referred to as source parameters. Classical techniques for determination of source parameters are

71 based on the modelling of body wave displacement spectra, that exhibit a flat level followed by a

72 power-law fall-off (Brune, 1970; Madariaga, 1976; Kaneko & Shearer, 2014). Uncertainty in

73 source parameters depends on the knowledge of the Green's function, with a strong correlation

74 between the anelastic attenuation and the source spectral fall-off (Abercrombie, 1995). This

75 correlation can be correctly handled in the computation of uncertainties, using Bayesian

76 approaches (e.g., Supino et al., 2019) or reduced, using small earthquakes as Empirical Green's

77 functions (EGF) (Prieto et al., 2004; Abercrombie & Rice, 2005) or data driven attenuation

78 functions (Oth et al., 2007).

79 Different approaches have been proposed to apply classical strategies for source

80 parameter estimation to DAS data, converting strain-rate data in ground motion quantities

81 (acceleration, velocity, or displacement). When specific seismic phases dominate the DAS

82 section, acceleration can be directly obtained from strain rate correcting for the apparent phase

83 speed (Daley et al., 2016). The conversion to acceleration of dominant phases can be done using

84 a slant-stack transform, that enables source parameter estimation, even in near real-time for early

85   warning applications (Lior et al., 2021; 2023). However, only locally dominant phases can be

86   correctly converted with this technique, while energy of smaller amplitude phases is smeared

87   along the seismogram. This issue may become critical for some applications, since DAS data are

88   more sensitive to slow, scattered waves (Trabattoni et al., 2022) and show reduced amplitude for

89   phases travelling at high apparent speeds (Van Den Ende & Ampuero, 2021). Phase independent

90   techniques were also developed for converting strain into ground motion quantities based on F-K

91   rescaling (Wang et al., 2018) and space integration using deformation (Trabattoni et al., 2023).

92   These techniques are sensitive to the rectilinearity of the cable and introduce low-frequency

93   artifacts that must be filtered out. This may affect the low frequency content of seismic spectra

94   and bias the moment magnitude estimation. Nevertheless, they have been shown to provide

95   reliable estimations of Wood-Anderson local magnitude, which requires an accurate

96   displacement measurement above 1 Hz (Trabattoni et al., 2023).

97   Relative measurements of source parameters can be performed directly in the strain

98   domain using the EGF approach, when the seismic moment of a reference event is available

99   (Chen, 2023). However, this technique is limited to co-located events that differ in magnitude of

100   at least one point (Abercrombie et al., 2017). Alternative approaches exploit correlations

101   between measurements in the strain domain and source parameters. For instance, elastodynamic

102   energy rate from strain was shown to scale with the kinetic energy rate from seismic sensors

103   enabling for magnitude estimation from energy (Trabattoni et al., 2022), while peak strain-rate

104   was demonstrated to correlate with local magnitude (Yin et al., 2023).

105   In this study we develop a new strategy for computing source parameters in the strain-

106   domain, deriving an analytical formulation that links the source time function with the strain.

107   This formulation allows to evaluate the source parameters inverting strain integral amplitude

108   spectra. The manuscript is organized as follows. In Section 2 we present the new formulation,

109   together with the inversion strategy and the estimation of the average radiation pattern

110   coefficients, that account for the different sensitivity of the along-fiber strain with respect to the

111   displacement. In Section 3, the new technique is validated through an application to real data for

112   two case studies: a 150 km-long fiber offshore Chile and a 1.1 km-long fiber buried in a dry lake

113   inside the Irpinia Near Fault Observatory.

114 **2 Source modelling in strain domain**

115   **2.1 Far Field source radiation**

116   Evaluating source parameters from native DAS recordings requires a new formulation

117 that can directly digest dynamic quantities (i.e., strain or strain rate). This formulation can be

118 derived from the far-field radiation emitted by a seismic source and recorded at a receiver at a

119 hypocentral distance r on the Earth's surface.

120   In a homogeneous medium, the far-field displacement associated with a seismic event

121 and characterized by a source time function $I(t)$ (hereinafter referred to as STF) can be

122 described in spherical coordinates, separating P and S contributions (Haskell, 1964):

$$
\begin{aligned}
u_r &= \frac{\beta^2}{4\pi\alpha^3 r} sin2\theta cos\phi \; I\left(t - \frac{r}{\alpha}\right) \\
u_\theta &= \frac{1}{4\pi\beta r} cos2\theta cos\phi \; I\left(t - \frac{r}{\beta}\right) \\
u_\phi &= -\frac{1}{4\pi\beta r} cos\theta sin\phi \; I\left(t - \frac{r}{\beta}\right)
\end{aligned}
\tag{1}
$$

123   Here α and β are the P- and S-wave velocities respectively, while the STF $I(t) =$

124 $\iint D\left(\xi, t - \frac{r}{c}\right) dS(\xi)$ represents the integral over the fault surface S of the slip function D, which

125 depends on the retarded time due to wave propagation from the source to the receiver (e.g., Sato

126 & Hirasawa, 1973). We assumed a circular crack with fixed slip direction as source model

127 (Madariaga, 1976). The spherical coordinates (θ the colatitude; ϕ the longitude) are defined on a

128 Cartesian reference frame W centered on the fault, where x and z are the along-slip and fault-

129 normal directions, respectively. Here, x and z also represent the directions of the two couples of

130 forces responsible for the earthquake rupture. The three angular functions in equation (1) are

131 indicated respectively as $P(\theta, \phi)_P$, $P(\theta, \phi)_{SV}$, $P(\theta, \phi)_{SH}$, and correspond to the far-field

132 components of the displacement radiation patterns.

133   We derived equation (1) to evaluate the strain at the receiver (see Supplementary Text

134 S1). Ruling out the contributions that decay faster than $1/r$ (far-field approximation), we obtain:

$$\varepsilon_{rr}^{FF} = \frac{\beta^2}{4\pi\alpha^3 r} P(\theta,\phi)_P \frac{\partial I\left(t - \frac{r}{\alpha}\right)}{\partial r}$$

$$\varepsilon_{r\theta}^{FF} = \frac{1}{8\pi\beta r} P(\theta,\phi)_{SV} \frac{\partial I\left(t - \frac{r}{\beta}\right)}{\partial r} \tag{2}$$

$$\varepsilon_{r\phi}^{FF} = -\frac{1}{8\pi\beta r} P(\theta,\phi)_{SH} \frac{\partial I\left(t - \frac{r}{\beta}\right)}{\partial r}$$

135   where ε^{FF} is the far-field strain tensor in spherical coordinates. This representation

136   preserves the separation between P and S contributions.

137   For a homogeneous medium, the radial derivatives of the STF can be written as a

138   function of their time derivatives:

$$\frac{\partial I\left(t - \frac{r}{c}\right)}{\partial r} = -\frac{1}{c} \frac{\partial I\left(t - \frac{r}{c}\right)}{\partial t} \tag{3}$$

139   where c is the wave velocity of the observed phase. Replacing (3) in (2) and computing

140   the time integral of the strain $\xi = \int \varepsilon dt$, we get

$$\xi_{rr}^{FF} = -\frac{\beta^2}{4\pi\alpha^4 r} P(\theta,\phi)_P I$$

$$\xi_{r\theta}^{FF} = -\frac{1}{8\pi\beta^2 r} P(\theta,\phi)_{SV} I \tag{4}$$

$$\xi_{r\phi}^{FF} = \frac{1}{8\pi\beta^2 r} P(\theta,\phi)_{SH} I$$

141   In the above equation we omitted the dependence of the STF on the retarded time. For a

142   1D layered model, this formulation is still a solution of the problem where the velocity c in (3)

143   represents an average velocity beneath the receiver, and (4) becomes (Aki & Richards, 2002):

$$\xi_{rr}^{FF} = -\frac{\beta_S^2}{4\pi\alpha_S^3 \alpha_R \, r} \sqrt{\frac{\alpha_S \rho_S}{\alpha_R \rho_R}} P(\theta,\phi)_P \, I$$

$$\xi_{r\theta}^{FF} = -\frac{1}{8\pi\beta_S\beta_R r} \sqrt{\frac{\beta_S \rho_S}{\beta_R \rho_R}} P(\theta,\phi)_{SV} \, I \tag{5}$$

$$\xi_{r\phi}^{FF} = \frac{1}{8\pi\beta_S\beta_R r} \sqrt{\frac{\beta_S \rho_S}{\beta_R \rho_R}} P(\theta,\phi)_{SH} \, I$$

144   with subscripts S and R indicating that the value is computed at the source and receiver

145 locations.

146   The strain integral is proportional to the STF as for the far-field displacement, enabling

147 for the inversion of ξ amplitude spectra to estimate the source parameters. It is worth to note that

148 equation (5) shows a larger sensitivity of DAS to the shallow velocity structure beneath the

149 cable, as compared to the displacement formulation.

150

151   **2.2 Spectral modelling**

152   To estimate the source parameters, we transformed eq. (5) in the frequency domain, to

153 get the spectral amplitude $\tilde{X}(\omega) = |FFT(\xi(t))|$. Separating the source $\tilde{S}(\omega)$ from the

154 propagation and site effect terms, respectively $\tilde{G}(\omega)$ and $\tilde{Z}(\omega)$, leads to (e.g., Baltay and Hanks,

155 2014):

$$\tilde{X}(\omega) = \tilde{G}(\omega) \cdot \tilde{S}(\omega) \cdot \tilde{Z}(\omega) \tag{6}$$

156   The Green's function $\tilde{G}(\omega)$ for a layered medium and a frequency independent quality

157 factor Q^c can be written as

$$\tilde{G}(\omega) = \tilde{K}^c A^c e^{-\left(\frac{\omega T^c(r)}{2Q^c}\right)} \tag{7}$$

158       $A^c(r) = 1/r$ is the geometrical spreading contribution and $T^c(r)$ is the source-receiver

159 travel time for the selected phase c. The factor $\tilde{K}^c$ writes:

$$\tilde{K}^c = \frac{\bar{B}_c^{FF} F}{8\pi \rho_S^{1/2} \rho_R^{1/2} c_S^{5/2} c_R^{3/2}} \tag{8}$$

160   In the above formula, F is the free surface contribution, ρ the density, also evaluated at

161 the source and receiver locations, and $\bar{B}_c^{FF}$ the mean radiation pattern that averages the

162 directivity effects of the different cable segments along all possible fault orientations. We assume

163 $F = 2$. The radiation pattern is discussed in detail in the next section.

164   For $\tilde{S}(\omega)$ we adopted a generalized Brune model (Brune, 1970):

$$\tilde{S}(\omega) = \frac{M_0}{1 + \left(\frac{\omega}{\omega_c}\right)^\gamma} \tag{9}$$

165   This function depends on the seismic moment M_0, proportional to the plateau level of the

166   spectrum at low frequency, the corner angular frequency ω_c that separates the long wavelengths

167   coherently propagating away from the crack from the interfering small wavelengths, and the

168   decay spectral fall-off γ.

169   Finally, the site term $\tilde{Z}(\omega)$ was assumed to follow an exponential decay (Anderson &

170   Hough, 1984):

$$\tilde{Z}(\omega) = e^{-\frac{\omega k^c}{2}} \tag{10}$$

171   where k^c is local attenuation coefficient.

172   Following Supino et al. (2019), we inverted the amplitude spectra with a probabilistic

173   Bayesian approach (Tarantola, 2004) where the best parameter evaluation and uncertainties come

174   from the integration of the a-posteriori joint Probability Density Function (PDF) in the parameter

175   space. In the general formulation of the inverse problem, we can retrieve up to 5 parameters: the

176   source parameters M_0, $f_c = \omega_c/2\pi$ and γ (f_c is the corner frequency); the regional attenuation

177   factor Q^c and the local attenuation coefficient k^c. The search for maximum of the PDF is

178   performed using a basin-hopping technique on Markov chain paths (Supino et al., 2019).

179   Correlation exists between the source and propagation parameters of the forward operator used

180   to model the spectra (eqs. 6-10), with model-dependent coefficients (Supino et al., 2019). A

181   formal treatment of the corresponding uncertainty is therefore needed to obtain reliable solutions

182   of the inverse problem (see Abercrombie, 2021 for a complete review). While the probabilistic

183   approach used in this study provides source parameter estimates with uncertainties accounting

184   for between-parameter correlations, the epistemic uncertainty related to the propagation and

185   source time function models clearly affects our estimates.

186   **2.3 Radiation pattern**

187   The average description of the radiation pattern for the displacement (Boore &

188   Boatwright, 1984) cannot be simply extended to fiber recorded strain, due to limited azimuthal

189   sensitivity of the DAS. The cable allows to recover only one out of the six components of the

190   symmetric tensor ξ, while a three-component instrument provides a complete description of the

191   displacement. In the case of DAS, we averaged the radiation pattern over all the possible fault

192   orientations, and also over all the possible directions of the fiber cable on Earth's surface.

193   A generic direction of a ray emitted from the source can be described by the take-off and

194   azimuth angles (θ, ϕ), in the reference W centered at the hypocenter. This ray intercepts a

195   portion of the fiber at the Earth surface, whose local orientation can be described by a different

196   couple of angles (θ', ϕ') in the same reference frame W. To account for these new additional

197   degrees of freedom, the average is performed over the focal sphere and all the possible directions

198   of the fiber relatively to the source. This yields:

$$\bar{B}_c^{FF} = \frac{1}{16\pi^2} \int_0^{2\pi} \int_0^{\pi} \int_0^{2\pi} \int_0^{\pi} |A_{1i}P(\theta,\phi)_c A_{j1}^T| \sin\theta \sin\theta' d\theta' d\phi' d\theta d\phi \tag{11}$$

199   Here the matrix A accounts for the rotation of the spherical frame from (θ, ϕ) to (θ', ϕ')

200   (see Supplementary Information, Text S2). The terms $P_{ij,c}$ are the angular functions defined in

201   eq. (2). The contributions associated with P and $S = (SV + SH)$ waves can be separated. The

202   integral (11) can be evaluated numerically, leading to:

$$\begin{aligned} \bar{B}_P^{FF} &= 0.2586 \\ \bar{B}_S^{FF} &= 0.2518 \end{aligned} \tag{12}$$

203   As an example, we show in Figure S1 (Supplementary material) S-wave contributions

204   recorded by fibers oriented along the three-coordinate axes of the reference frame W, as a

205   function of the take-off and azimuth.

206

207   **3 Data and Results**

208   The proposed technique was applied to evaluate the source parameters on two different

209   datasets. First, we considered DAS data recorded by a 150-km long marine telecommunication

210   cable, located offshore the Chilean margin; then we applied the same technique to earthquakes

211   recorded by a 1.1 km-long cable deployed in the Southern Apennines (Italy).

3.1 Submarine DAS data offshore Chile

DAS data in Chile were recorded during the month of November 2021, when an interrogator unit (OptoDAS – Alcatel Submarine Networks) was connected to a submarine fiber optic telecom cable, operated by the GTD group and linking Concón to La Serena. The DAS was able to sense 150km-long portion of the cable. A map of the cable is represented in Figure 1b and in Figure S3 of Supplementary Information. Data were processed using a gauge length of 8.16 m with a repetition rate of 625 Hz and a spatial sampling of 1.02m averaged over 4.08m. They were further decimated to a sampling rate of 125 Hz and a spatial sampling of 65.28m. In Figure 1a an example of DAS recording along the cable is shown for a $M_L 2.9$ event occurred at $23km$ depth, at minimum and maximum distances from the cable of $24km$ and $93km$ respectively (ID: 20211119T055900, see Data availability statement for catalog reference), along with a zoom on a strain rate record from a single channel.

For the analysis, we focused on a subset of 55 events, whose local magnitude M_L ranges between 2.5 and 4.3, also recorded by the seismic network from the Centro Sismologico National (CSN). These events are representative of the magnitude and distance ranges of earthquakes occurred during the period of the experiment. Origin times from CSN catalog were used as reference times to create three-minute-long DAS records.

We individuated the S-wave arrival time on single traces using the machine learning algorithm Earthquake Transformer - EqT (Mousavi et al., 2020). The associator GaMMA (Zhu et al., 2022) was then applied to evaluate the consistency of the S-picks along the fiber, based on the apparent wave velocity. Examples of automatic picking and detection on DAS data are shown in Supplementary Information Text S3). Accuracy on the picks was shown to be sufficient for extraction of the S window for spectral analysis (Scotto di Uccio et al., 2023). The study focused on the inversion of S phase, which represents the dominant contribution since horizontally deployed fibers are less sensitive to P wave phases owing to their high apparent velocities (Papp et al., 2017; Trabattoni et al., 2022). Moreover, in sedimentary areas, the P-wave train is generally polluted by S-waves converted at the bedrock/sediment interface (Trabattoni et al., 2023).
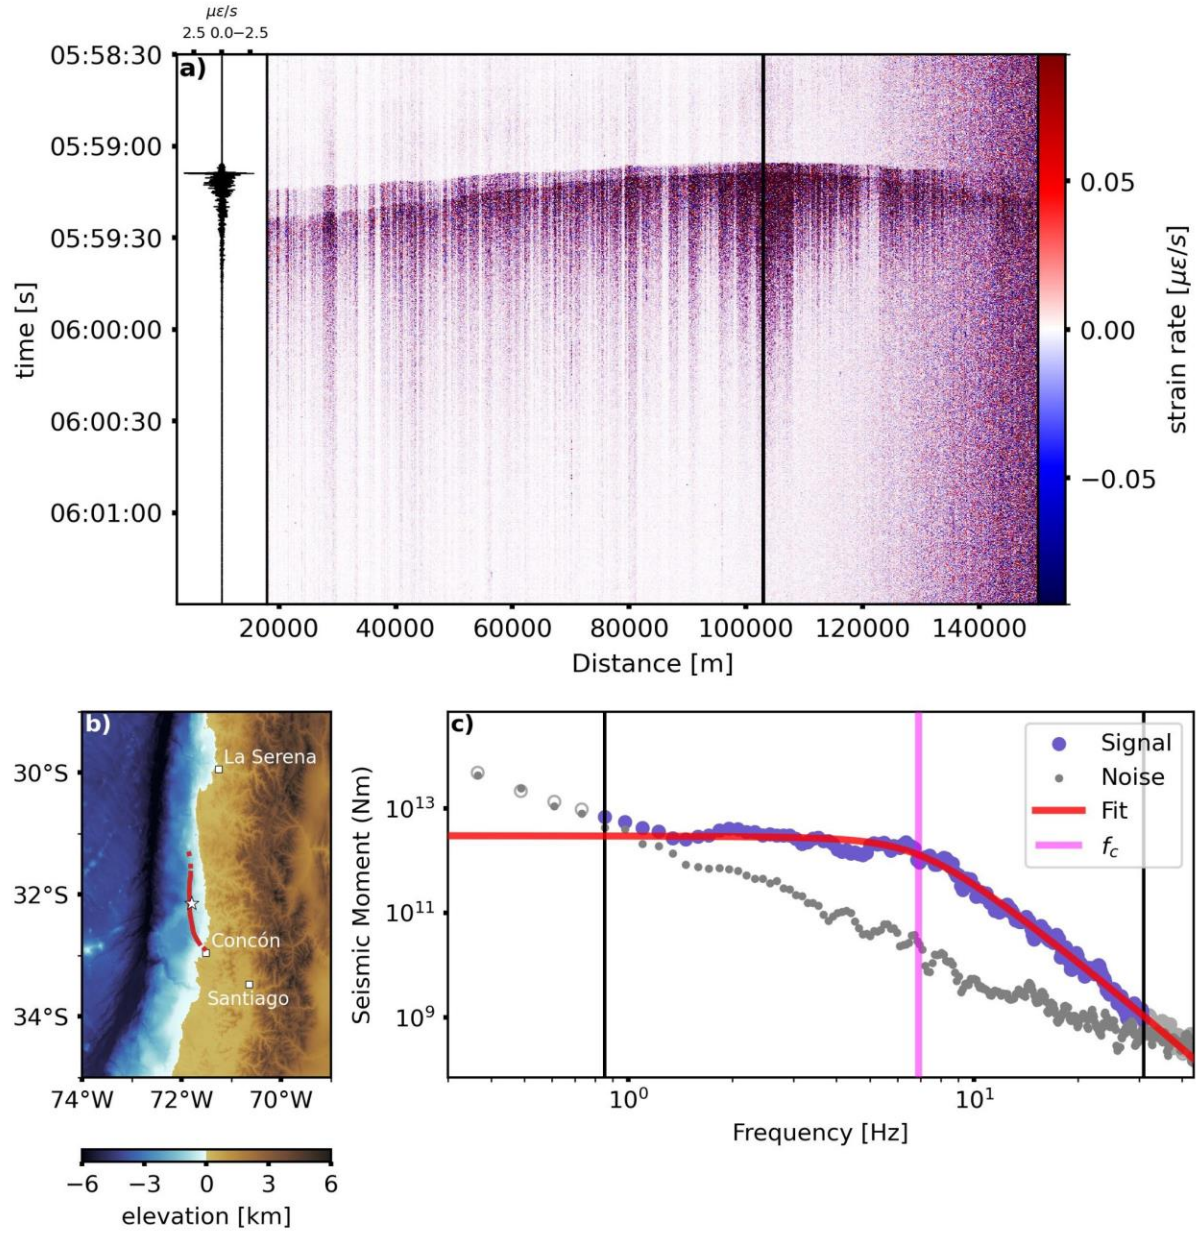

Figure 1: (a) Space-time representation of the strain rate wavefield, bandpass filtered between 1 and 30 Hz, recorded at the fiber for a $M_L 2.9$ event occurred on the 2021/11/19. The black line marks the channel, whose time signal is shown on the left side. **(b)** Event location (yellow star) with respect to the fiber section used in the analysis (filled red curve). **(c)** S-wave spectrum of the selected channel (blue points, gray open circles) and of the noise (gray points) are represented. The vertical black lines individuate the frequency domain where the SNR is larger than the selected threshold and the inversion was performed. The red curve is the best-fit spectrum obtained from the inversion. The flat level at low frequencies indicates seismic moment estimate M_0 at the channel, while the magenta line marks the corner frequency f_c.

249   Before inversion, data were band pass filtered between $0.05 Hz$ and $40 Hz$ to mitigate the

250   influence of low frequency oceanic noise and high frequency sources of noise, and then the

251   highest quality channels along the cable were selected based on their Signal to Noise Ratio

252   (SNR). This latter quantity was evaluated by computing the ratio between the 90th percentile of

253   the amplitude in a 6s window after the S arrival time, and the 90th percentile of the amplitude in

254   a noise window of 20s before the origin time of the event. We selected channels with SNR>4,

255   and we processed events only if the number of available channels was larger than 200, that

256   represents almost one tenth of the total number of channels. Following this approach, we were

257   able to estimate the source parameters for 37 events. A map of these events is represented in

258   Figure S3 of Supplementary Information.

259   To model the spectral amplitude expressed in eq. (8) we used $c_S = 4500$ m/s and

260    $Q = 800$ as provided by the tomographic model of Marot et al., (2014). Also, we set $\rho_S = \rho_R =$

261   2700 kg/m^3 and the S-velocity at the receiver $c_R = 400$ m/s, according to the analysis of f-k

262   diagrams. For this dataset, we did not observe a saturation of the corner frequency at low

263   magnitudes and thus we considered negligible the site contribution of eq. (10). The length of the

264   signal used to evaluate the spectra depends on the event magnitude, to consider the size

265   dependence of the source duration (Trifunac & Brady, 1975; Supplementary Information Text

266   S5). This window also contains a small portion (10%) of signal before the S-pick to account for

267   uncertainties in arrival times.

268   In Figure 1c we represent the amplitude spectrum of a channel from the DAS records

269   (See supplementary Information Text S6 for more examples). The signal exhibits a clear plateau

270   level at low frequencies and a decay in the high frequency band. For each channel the inversion

271   is performed in a specific frequency band (delimited in the figure by the vertical black lines),

272   where the spectral amplitude of the signal overcomes the noise of a factor larger than 3.5. Low

273   SNR typical of DAS recordings (Lellouch et al., 2020) results in narrower frequency band to be

274   used for the inversion, as compared to standard seismic instruments.

275   Seismic moments and corner frequencies evaluated from the selected dataset exhibit near

276   to constant stress drop (Figure 2a). Using the relationship from Keylis-Borok, (1959):

$$\Delta\sigma = \frac{7}{16}\left(\frac{f_c}{C_k \beta}\right)^3 M_0 \tag{13}$$

277   and the geometrical factor of $C_k = 0.26$ from Kaneko & Shearer (2014), the averaged

278   stress drop was estimated to $\Delta\sigma = (0.8 \pm 0.6)$MPa, which is comparable to what found for

279   earthquakes in central Chile (Şen et al., 2015). We also compared moment magnitude

280   estimations with those obtained from the inversion of seismic records from on land CSN stations.

281   We found great coherency between estimates (Figure 2b). This indicates that the observed

282   plateau level at low frequencies is representative of the event moment release and is not

283   significantly affected by instrumental effects. Furthermore, we also compared moment

284   magnitude obtained from DAS data with local magnitudes from CSN catalog (Supplementary

285   Information Text S7; Figures S6) showing that our estimations are consistent with M_L and that

286   for this range of magnitudes the low frequency plateau is coherent with the energy content of the
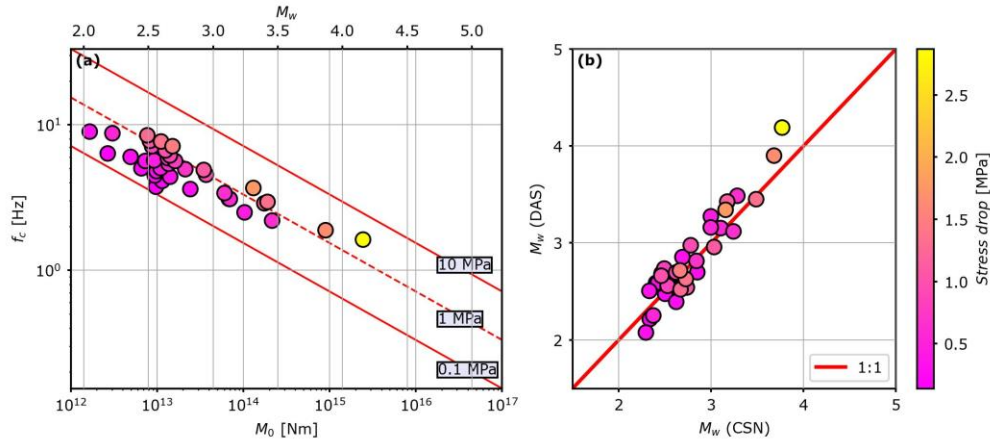

287   signal.

288

289   **Figure 2: (a)** Corner frequency as a function of the seismic moment for the Chilean dataset, exhibiting almost

290   constant stress drop scaling, with average value of (0.8 ± 0.6)MPa and values ranging between 0.1 MPa and 3 MPa.

291   **(b)** Comparison between DAS and CSN moment magnitudes; CSN Mw are obtained from inversion of seismic

292   records from in land stations for the same dataset. Estimations exhibit a scaling consistent with a 1:1 relationship.

293   The consistency of the modeling of the amplitude decay with the event distance could be

294   asserted by taking advantage of the dense spatial sampling provided by the DAS technology. For

295   each event, we computed the residuals for both M_w and f_c at each channel, by removing the

296   average value estimated for the whole cable from the single channel estimate. We grouped

297   residuals by hypocentral distances in bins of 1 km (from 20 to 150 km) regardless of the event or

298   channel. The median and standard median absolute deviation (SMAD) for residuals were

299   computed for each bin as a function of the hypocentral distance (Figure 3). The estimations are

300   unbiased in the whole distance range. Only for distances below $40 km$ the moment magnitude

301 exhibits residuals slightly larger than zero; this overestimation of the geometrical spreading

302 correction could be ascribed to possible uncertainty in event location.

303

304 **Figure 3:** Analysis of the source parameters residuals as a function of the hypocentral distance. Bold lines represent

305 the median of the residuals for each distance bin, while the error is represented by the Standard Median Absolute

306 Deviation (SMAD). **(a)** M_w residuals exhibit a slight bias at short distances (<40 km), while no other trend is evident

307 at other distances. **(b)** f_c residuals are unbiased, showing that the exponential decay as a model for regional

308 attenuation well describes the spectral decay for a wide range of hypocentral distances.

309   The possibility of evaluating source parameters at thousands of different stations comes

310 with variability of spectral fits and thus in source parameter evaluations, as shown in Figure 3, as

311 consequence of both propagation and different coupling conditions along the cable (See

312 Supplementary Information Text S8, Figure S7).

313   **3.2 Southern Apennines DAS measurements**

314   In contrast to Chilean events, the Southern Italy DAS survey focused on smaller

315 microseismic events ($M_L \leq 2.5$), that represent a challenging test for the resolution of source

316 parameters. The data were acquired during a 5-month experiment, involving a DAS interrogator

317 (Febus A1-r) connected to a 1.1km-long L-shaped fiber optic cable, buried into a shallow trench

318 ($0.3m - 1.0m$) in a dry lake near the town of Colliano (Figure 4b). The instrument was set to

319 work with a sampling rate of 200Hz, further downsampled to 100Hz, and a spatial sampling of

320 2.4m, with a gauge length of 4.8m (more details in Trabattoni et al., 2022).

321   The site of the installation was near the emergence of the main segment of the normal

322 fault system that generated the devastating 1980 $M6.9$ Irpinia earthquake in the Southern

323 Apennines. The area is nowadays monitored by the Irpinia Near Fault Observatory (INFO),

324 (Chiaraluce et al., 2022) that detected several dozens of events during the deployment period.

325   Figure 5 shows the recordings of a $M_L2.3$ event occurred on 2021/09/20 at 13:07:55 and

326 reveals the specific propagation pattern due to the shallow sedimentary layering, as described in
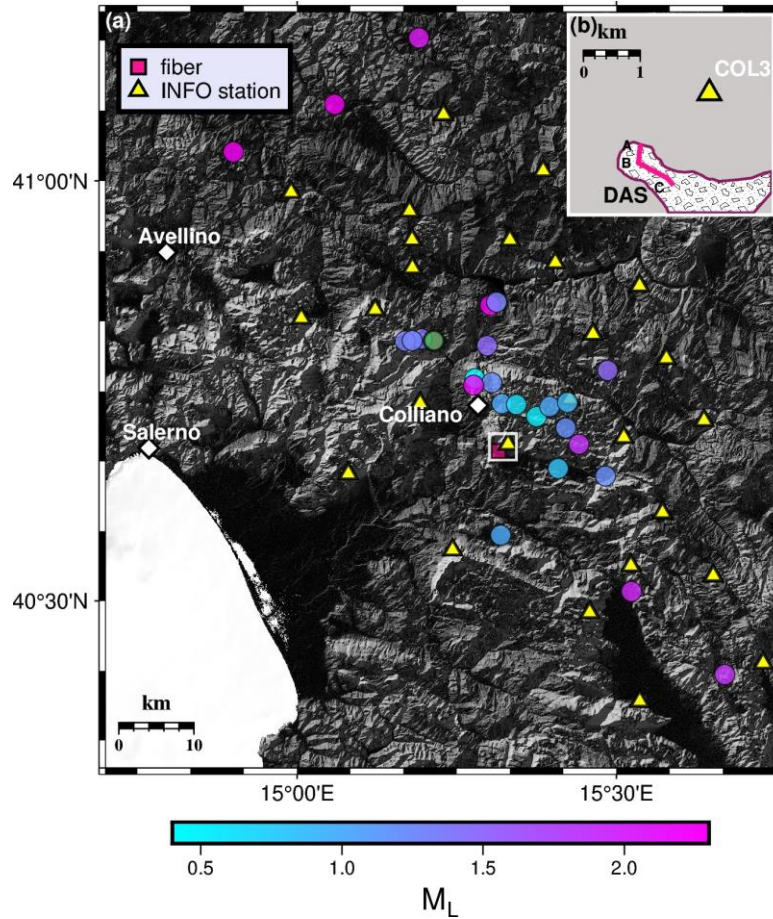

327 Trabattoni et al. (2022).

328

Figure 4*:* **(a)** Map showing the location of the fiber (white square) and the events recorded by the DAS interrogator

(color code based on their M_L). The green point marks the event represented in Figure 5 (almost $20km$ away from

the installation site). Panel **(b)** depicts the area contained in the white square, showing the L-shaped fiber (magenta

line), with a kink in B, and the nearest INFO station COL3 (yellow triangle), located at less than $2km$ from the

interrogator. The white-pattern area represents the dry lake where the cable was buried for the experiment.

334

335   As for the Chilean dataset, we considered events in the local bulletin and extracted

336 related DAS waveforms from the continuous data stream. We limited our analysis to the

337   channels of the section AC, excluding few low-quality channels at the beginning and the end of

338   the cable. Data were filtered between $0.1Hz$ and $30Hz$ to isolate the earthquake signal from

339   environmental and anthropogenic noise and to perform a SNR based channel selection as

340   previously described for the Chilean case.

341

342   **Figure 5***:* The space-time representation of the strain rate wavefield, filtered between 1 and 30 Hz, recorded by the

343   DAS system for a M_L 2.3 event occurred on 2021/09/20. The black filled line marks the channel, whose time signal

344   is shown on the left side, while the dashed black lines individuate specific points along the cable, shown in Figure

345   4b.

346

347   For this dataset, we restricted the source parameters estimation to channels satisfying

348   SNR>8, resulting into a catalog of 26 events that meet the SNR criterion at a minimum number

349   of 40 channels. This curated dataset (Figure 4a) includes events with local magnitude spanning

350   from 0.4 up to 2.3, and hypocentral distances from $6km$ to $60km$ (see Data and Availability

351   statement for complete catalog information; magnitude and distance distribution of the events is

352   represented in Figure S8b) Amplitude spectra were computed on 5s time windows around the S-

353   pick (from 0.5s before to 4.5s after the S-pick), this latter obtained from the nearby station

354   (COL3, distance from the fiber $< 2km$, see Figure 4b).

355   By analyzing the spectra of the events along the fiber, we observed that the spectral decay

356   following the plateau level starts around an apparent corner frequency of $5.5Hz$ (grey circles,

357 Figure 6b), irrespective of the event magnitude and location and of the channel along the fiber

358 (Figure 6a). The saturation of the apparent corner frequency and the following decay can be

359 ascribed to local site effects (e.g., Hanks, 1982) because spectral fall-offs due to the source and

360 to the anelastic attenuation are both expected to show a cut-off frequency dependent on

361 magnitude (source corner frequency) and distance (regional anelastic attenuation; eq. (7)).

362 Moreover, assuming an average value of the quality factor Q for the area ($Q = 230$; Zollo et al.,

363 2014; Amoroso et al., 2017) the spectral decay due to the anelastic attenuation is generally

364 expected to start at frequencies higher than $5.5 Hz$ for the range of hypocentral distances

365 associated with events recorded at the fiber.

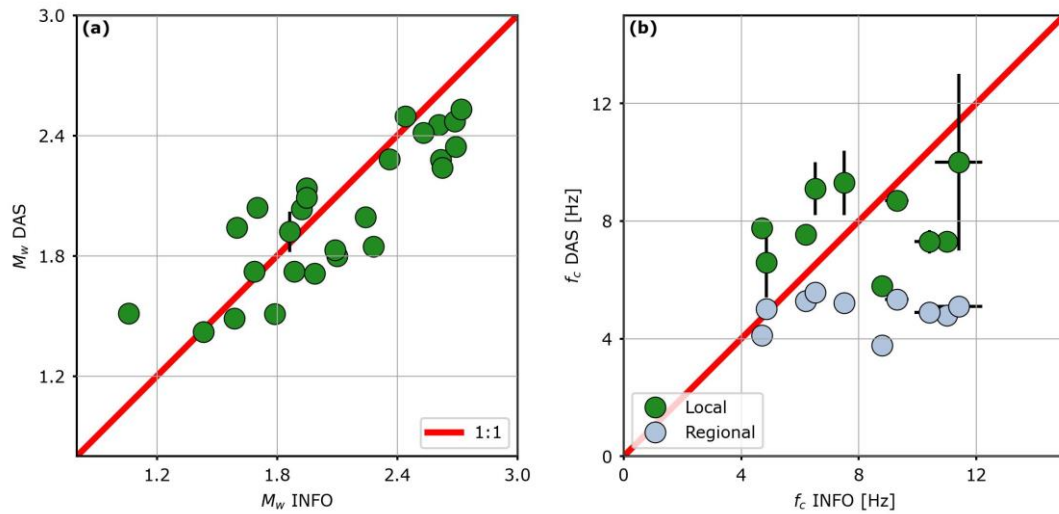

366

367 **Figure 6: (a)** Moment magnitude comparison between estimates from DAS and from INFO network. Estimates

368 from DAS data follow a 1:1 scaling (red line) when compared with standard seismic station results. **(b)** Corner

369 frequency comparison between DAS and local network. Without correction for local site effects (gray dots) DAS

370 estimates saturate resulting into an apparent f_c around $5.5 Hz$. After the correction for local site effects (green dots),

371 the two estimates become comparable.

372 We modelled the local site effects using the local attenuation coefficient k^c, as described

373 in eq. (10) (Anderson & Hough, 1984; Butcher et al., 2020; Ktenidou et al., 2014, 2015). To

374 infer an average value for k^c, we selected small magnitude events in the dataset ($M_w < 2.0$) for

375 which the source corner frequency is expected to be much larger than the observed cut-off

376 frequency (Zollo et al., 2014). For these events, after removal of regional anelastic attenuation

377 assuming $Q = 230$, we fit the logarithm of the amplitude spectra as a function of the frequency

378 to evaluate k^c for each channel and each event (Figure 7a). In Figure 7b, we represent the spatial

379 variability of k^c along the fiber. The local attenuation coefficient has its maximum in the central

380 section of the cable, decreasing almost linearly toward the ends of the cable, and possibly

381 mimicking the shape of the lake basement. We computed the median and the SMAD values from

382 k^c single-channel averages, leading to $\bar{k}^c = (0.08 \pm 0.02)$s.

383

384 Since the k^c estimates are not available or they are not equally robust at all channels, due

385 to the coupling and rapid changes in direction of the cable, the median value was used in the

386 source inversion of the largest magnitude events $(M_w > 2.0)$ to remove local site effects from

387 their observed spectra, thereby evaluating their seismic moment and source corner frequency.

388

389 **Figure 7:** **(a)** Example of the linear fit (red curve) estimated on the log-linear spectrum (green circles) of one of the

390 smallest events in the dataset $(M_w < 2.0)$ at a specific channel of the fiber to obtain a single-channel estimate of k^c.

391 The spectrum is fitted in the frequency band where the SNR exceeds the imposed threshold of 3.5 (black vertical

392 bars). **(b)** k^c variability along the cable represented by the mean (blue green curve) and standard deviation (shaded

393 area). The dashed black line individuates the position where the cable has a kink (Figure 4b). **(c)** Log-log spectrum

394 at one channel for a $M_w 2.3$ event after the site contribution was removed using the averaged value of k^c along the

395 cable. The image has the same color code described in Figure 1. The f_c estimation is marked by a vertical magenta

396 line. (Time traces of the two events are shown in Supplementary Information Text S10).

397 We compared source parameters estimation from DAS and INFO network seismic

398 records (Figure 6). M_w estimations from DAS were found to be consistent in the analyzed

399 magnitude range with the ones retrieved from the INFO network, obtained inverting local

400 seismic records (Fig. 6a). The correlation between both estimates is lower than in the Chilean

401   case. For Southern Apennines, this can be attributed to the short length of the cable that does not

402   capture the variability of the M_w estimates due the distance and azimuth. Corner frequencies

403   recovered from DAS saturate at 5.5 Hz without the site correction (gray dots, Figure 6b) but are

404   compatible with the ones obtained from INFO seismic stations when modelling the site

405   attenuation for the largest events (green dots, Figure 6b).

406

4 Discussions

408   The new formulation of the far field strain spectra developed in this work does not

409   require to convert waveforms from strain to velocity (e.g., Wang et al., 2018; Lior et al., 2021;

410   Trabattoni et al., 2023) and can be directly applied to raw DAS data. Signal manipulation during

411   the conversion to kinematic quantities could modify the seismic spectra. For example, the low-

412   wavenumber accuracy of the conversion of the strain rate to displacement by direct integration is

413   limited by the rectilinearity of the fiber (Trabattoni et al., 2023). Also, the use of the slant-stack

414   transform for the evaluation of the dominant apparent velocity (Lior et al., 2021, 2023), only

415   allows to correctly convert the most energetic phase, and the spurious contribution of other not

416   well-integrated, superimposing phases, cannot be easily evaluated. The proposed strategy also

417   disengages from the colocation hypothesis and the knowledge of parameters for a reference

418   event, as required for EGF based approaches (Chen, 2023) that also rely on raw DAS data.

419   From the theoretical formulation, we retrieve an enhanced sensitivity of strain

420   measurements to the shallow structure beneath the cable, with a dependence on the wave

421   velocity at three-halves power instead of one-half, as compared to the displacement formulation.

422   Knowledge of a-priori shallow S (and P) wave velocities is thus relevant to avoid biases in the

423   estimation of the seismic moment. It is worth to note that this velocity also enters (as apparent

424   velocity) in the conversion from strain-rate to acceleration (Daley et al., 2016).

425   We also report average radiation pattern contributions which are more than twice smaller

426   than the ones retrieved for seismometer records, in agreement to the lower and complex

427   directional sensitivity of DAS to body waves (Martin et al., 2021). Moreover, the presence of

428   additional nodes in the radiation pattern diagrams suggests cable deployments with changes in

429   the fiber orientation, to improve the resolution in the source parameters.

430   Finally, the proposed approach, when integrated in a probabilistic formulation, can be

431   fully automated, with the quality of the solutions based on the shape of the a-posteriori

432   probability density functions (Supino et al., 2019). Also, when extending this approach to the P-

433   waves, this strategy could be applied in real-time, when few seconds of early P wave signal are

434   available (e.g., Caprio et al., 2011).

435   Validation of this approach on Chilean dataset ($M_L = 2.6 - 4.3$) shows a reliable

436   estimation of source parameters, comparable with results from standard seismometers. We do not

437   observe any dependence of parameters on the hypocentral distance, enabling DAS to

438   characterize the source of events in wide range of hypocentral distances. Moreover, source

439   parameters exhibit scale invariant stress drop with an average value of $(0.8 \pm 0.6)MPa$,

440   consistent with the values retrieved for events in Central Chile.

441   In the second application we analyzed smaller size events ($M_L = 0.4 - 2.3$), using DAS

442   data recorded on a much shorter ($1.1km$) cable installed in the active tectonic environment of

443   Southern Apennines (Italy). We found good agreement for moment magnitude estimates from

444   DAS as compared to the ones from standard seismic stations in the explored magnitude range.

445   Because of the specific installation site (a dry lake), local attenuation plays a crucial role,

446   masking the effect of the source size in the spectrum. Using a parametric EGF-based approach,

447   we estimated an average local attenuation coefficient $\bar{k}^c = (0.08 \pm 0.02)$ s that is comparable

448   with the values estimated in very soft soils (Ktenidou et al., 2015). Also, the analysis of the

449   variability of k^c shows linear trends with distance along the cable, coherent with the increase in

450   attenuation with the distances from the tips of the basin (Trabattoni et al., 2022), and that can be

451   correlated with the depth of the structure (Campbell, 2009). When removing this attenuation

452   from the spectra of the largest magnitude events in the catalog ($M_w > 2$), we were able to

453   resolve the corner frequencies, that now result to be coherent with the estimates from velocity

454   seismograms.

455   The estimation of the k^c parameter for the Southern Italy dataset indicates the possibility

456   to use DAS data to infer mechanical properties of the shallow layering, beyond the source

457   parameters when the site-associated spectral cut-off occurs in the central part of the available

458   frequency band for the inversion. This condition does not apply for the Chilean data, where we

459   report no saturation of the corner frequency for the analyzed set of events.

460   Epistemic uncertainty associated with regional attenuation, corrected by a frequency

461 independent quality factor, site effects described through the k^c parameter, and average radiation

462 pattern coefficients may result in an increase of the variability of source parameters along the

463 fiber.

464   When analyzing the residuals in source parameter estimation, we did not observe any

465 dependence on the distance, indicating a consistent description of the associated amplitude

466 decay. Frequency dependent site effects along the cable would be more difficult to analyze, since

467 they depend on the orientation of the fiber and the backazimuth of the events. Larger datasets

468 and complementary analysis, grounded on ambient noise and simulations, are required to relate

469 these effects to the morphology and velocity of the shallow layers (Bordoni et al., 2011).

470   Moreover, to take advantage of distributed estimations obtained through DAS, after

471 correction for attenuation and site, investigating residuals along the cable can bring information

472 on the variability of the radiation pattern, that can be used to constrain the focal mechanisms of

473 the events, in addition to polarities (Zahradník et al., 2001).

474   Working with DAS spectral amplitudes, especially for time integrated strain data,

475 displays unique instrumental noise, with coherent low frequency contribution that tightens the

476 bandwidth where the signal can be inverted (Lior et al., 2023). This issue is related to

477 instrumental properties and unwrapping errors rather than seismic information in the signal, and

478 could be mitigated with the ongoing evolution and increasing demand of distributed sensing

479 sensors. However, for events for which we estimated both seismic moment and event size (M_w

480 between 2.0 and 4.3) we report that the corner frequency lies in the middle of the frequency band

481 available for the inversion, allowing for an accurate estimation of source parameters as it is

482 demonstrated by the comparison with results from standard seismic instruments. For smaller

483 magnitude events, we were able to capture only the flat level of the spectrum, preventing from

484 the estimate of earthquake size. We might also expect a limitation in the use of DAS data for

485 source parameter estimation for events with magnitude larger than $4.5 - 5.0$ (not included in the

486 analyzed catalogs), where the expected corner frequency approaches the lower limit of the

487 informative frequency bandwidth. In this case, the inversion could provide biased estimates for

488 the moment magnitude, as compared to standard instruments.

489   Consistency of estimates between DAS and seismic data guarantees that the contribution

490   of secondary phases in the selected S-wave window, to which the DAS could be more sensitive,

491   does not introduce significant biases in the retrieved source parameters.

5 Conclusions

493   In this work we estimated source parameters from a spectral inversion of DAS data in

494   their native representation, based on a novel formulation describing the far-field radiation in the

495   strain domain. The theoretical modeling displays an enhanced sensitivity to the velocity structure

496   beneath the cable and the radiation pattern.

497   Including this model in a probabilistic framework for the inversion (Supino et al., 2019)

498   allowed us to estimate the moment magnitude and the corner frequency from two different

499   datasets, showing consistent values when compared to authoritative catalogs.

500   When analyzing data acquired from a $150 km$ ocean-bottom dark fiber cable near the

501   Chilean trench ($M_L = 2.6 - 4.3$), we found near to constant stress drop, with an average

502   estimate of $0.8 \pm 0.6 MPa$. Despite their natural variability, we report no biases of average

503   estimations of source parameters with hypocentral distance along the cable.

504   Application of the technique to microseismic data ($M_L = 0.3 - 2.3$) acquired in the

505   Southern Apennines (Italy) represent a challenging test for the achievable resolution in the

506   characterization of small earthquakes using DAS. We coherently estimated the seismic moment

507   in the whole magnitude interval. Site effects were shown to dominate the high frequency part of

508   the spectrum and need to be modelled and corrected for to retrieve the source extension for

509   events with $M_w > 2$.

510   The two case studies presented in this work reveal the high potential of DAS for source

511   characterization, while the dense spatial sampling could be a key ingredient for understanding

512   source parameters variability and their relationship with the rupture behavior and the local

513   structure. Nonetheless, fiber optic data require careful processing both for the peculiar signal

514   properties, and for the large amount of information necessitating efficient storage and handling

515   procedures.

516
